castle conference, and as such reflect both the merits and faults of the conference itself. At the same time, however, they present problems of their own. I was about to say that they are the academic equivalent of the book of the film, but on reflection it would be more true to say that what we actually have here in part is the book of the film of the book. In other words, no small proportion of the material presented has been published before in other forms.

It is time that the pressures—of tradition, commercialism, the ego, or whatever—to manufacture tomes such as these were resisted more often, not least because the result is self-defeating. It is quite reasonable, of course, that conference organisers should seek to make available to nonparticipants something of what the privileged few have found useful or enjoyable. But when such proceedings are produced incompleteness may be a virtue. It would have been far more profitable for everyone if Tarling and Runcorn had commissioned a small group of the best scientists and writers involved to distill the essence of the 87 original papers into a book of 200 pages or so, avoiding overlap, the bad, the indifferent and the peripheral, and perhaps even restricting the coverage. People, rather than merely libraries, would then have bought the book and read it. As it is, "so it must be, for now all length is torture". As Mark Antony might say.

PETER J. SMITH

Experimental X rays

X-Rays in Atomic and Nuclear Physics. By N. A. Dyson. Pp. xiii+380. (Longman: London, December 1973.) £8.

THIS book is the logical successor to Compton and Allison's *X-Rays in Theory and Practice*. The author emphasises the constant interest that has been maintained in the subject since the discovery of X rays by Roentgen in 1895, and points out that the succeeding years can be roughly divided into three eras, each twenty-five years long. The first of these, from 1895 to 1922, saw the laying of the foundations, and a multitude of experiments were performed with the prime purpose of elucidating the properties and behaviour of X rays. The second period, 1922 to 1945, was involved with the development of X-ray spectroscopy, and the design and construction of sensitive detection systems. The third period, from 1945 to the present day, has been concerned more with nuclear properties and with the physics of the stars. It is not often that a single branch of physics has kept up its momentum over such a long period and has, at the same time, been able to generate such important and wide-ranging offshoots as X-ray

crystallography, Auger spectroscopy, and Mössbauer spectroscopy.

After a brief historical introduction, the author covers his chosen field in six chapters: the continuous X-ray spectrum; characteristic X rays; experimental techniques for the study of X rays; the absorption and scattering of X rays; X rays in radioactive decay; and some additional fields of X-ray study. There follows a number of appendices giving numerical data, a comprehensive bibliography arranged chapter by chapter, and finally a subject index.

The bias of the book is towards the experimental side which is understandable, since much of the physics of X rays is well understood and documented. The chapter concerned with experimental techniques is particularly notable for its wealth of detail for the construction of a variety of devices for the detection of both hard and soft X rays. Each chapter is copiously illustrated with diagrams emphasising the nature of the results that can be obtained in the particular area under discussion.

The last chapter is in some ways the most interesting one because here the author changes pace and selects various areas in which X rays have been used (such as various sorts of microanalysis), are being used (such as the isotope effect in absorption and emission), or are likely to play a dominant part (such as plasma physics and astrophysics). When, to all this, is added such important areas as medical physics and industrial radiography, it is clear why the author's mood seems to be so buoyant and optimistic. Certainly his claim that not only have X rays had a great part to play in the past, but are likely to continue to do so is certainly justified.

The book is economically written, well illustrated and carefully produced. It should be made available in all scientific libraries, and should find a place on the shelves of any individual who is interested in the production, properties, and applications of short wave-length radiation.

P. J. WHEATLEY

All dating is relative

Recent Earth History. By C. Vita-Finzi. Pp. xii+138. (Macmillan: London and Basingstoke, October 1973.) £3.00 boards; £1.50 paper.

THIS slim volume has an inappropriate title, for this relates rather to the author's original intention "to write an account of the physical changes undergone by the earth during Holocene times . . .", as he states in his disarming preface. This book presents the contention that chronology should be based upon dating and not upon stratigraphy,

that is, that dating throughout earth history should be chronometric and not relative.

The author quotes the anonymous reviewer of an early draft of this book that "Palaeontology . . . and stratigraphy are humble and intellectually unexact-ing and nothing written by [the author] or anyone else can change this for a long time". Although obviously someone who knew very little of modern palaeontology and stratigraphy, that reviewer was probably correct in concluding that such a view would not be modified by this book's contents.

The author apparently understands that quantitative dating depends upon the resolving power of the particular method, but a failure to deal satisfactorily with Oakley's point that "All dating is in a sense relative", renders the book less than effective for its purpose. The dustcover's claim that the book is "clearly written and logically argued" is perhaps rather too obviously a commercial.

EDWARD A. FRANCIS

Many bodies

The Many-Body Problem. By W. E. Parry. (Oxford Studies in Physics.) Pp. x+217. (Clarendon: Oxford; Oxford University: London, December 1973.) £6.25.

DR Parry, in writing this book, had a very clearly defined and limited aim to which he has stuck rigorously. Assuming that his readers would have a knowledge of basic statistical physics and of Dirac's approach to quantum theory, he provides them with a large number of the mathematical techniques currently used for dealing with many-body problems and shows how they are related. Applications are introduced to illuminate the mathematics but only for this purpose. Readers are referred elsewhere for a fuller study of specific physical problems. The result is a well balanced, comparatively slim book containing a wealth of methods which include second quantisation, perturbation theory, Green functions, correlation functions, linear response theory, partial summation of diagrams, equations of motion, the drone-fermion representation in magnetism and the use of the variational principle.

Despite the large number of techniques introduced, the book has a uniformity which makes it easy to read and to relate one part to another. The point of departure (one I favour) is temperature-dependent perturbation theory for the grand partition function and other techniques are related to this. Expansions for the properties of the ground state are derived from this as a special case. This approach makes the

book particularly useful for solid state and liquid physicists but, perhaps less so for nuclear physicists.

The whole is characterised by great care and thoroughness. Motivation and the main line of attack are always made clear. Very rarely does a "let us consider" leap out at one from the dark. Despite this, Dr Parry does not shirk the difficulties. He provides full proofs of the various basic theorems including the sometimes tricky points but the mathematical completeness does not obscure the main argument. This makes the book, within its limit, self-contained. The exercises placed throughout the text enable the reader to test his progress. The approximations introduced, especially in the partial summation of diagrams, are carefully discussed. The result is a successful realisation of the author's aims and a book through the pages of which one's research students can safely be encouraged to roam.

G. RICKAYZEN

Prolific mathematician

The Art of Counting: selected writings. By Paul Erdős. Edited by Joel Spencer. (Mathematics of Our Time, vol. 5.) Pp. xxiii+742. (MIT: Cambridge and London, 1973.) \$22.50.

THIS handsome volume contains a selection of about 80 papers from the prodigious output of Paul Erdős. It was produced to celebrate the 60th birthday of this peripatetic genius, and the selection has been made with a view to illustrating his unique contributions in combinatorics. In this latter respect the editor's choice is only partially successful (and the title is somewhat deceptive); for as Turan points out in a short introduction, combinatorial ideas have characterised Erdős's work in other fields too, and notably so in the theory of numbers. There is a glimpse of this in the papers concerned with latin rectangles, especially in the joint paper (314) with Chowla and Straus where a famous conjecture of Euler about pairwise orthogonal latin squares is shown to be just about as false as can be by means of quite deep arithmetical arguments. But this is not intended as a criticism but rather as an encouragement to other devoted friends of Erdős to set about collecting other portions of his work, not only as a tribute but also as a great service to scholarship.

A charming essay of reminiscences by Szekeres introduces chapter 1, which contains a seminal paper by Erdős and himself demonstrating for the first time the power of Ramsey's theorem; and this is also the theme of chapter 8. Chapter 2 contains four survey articles in which Erdős poses and discusses unsolved problems in his own inimitable style, and in the process charts the de-

velopment of the subject. His matchless ability to generate problems and conjecture results, and his unselfish willingness to share his mathematical concerns with anyone prepared to have a go, have inspired his contemporaries, great and small alike, for many years; in these lectures we come as close as we can in print to his essential mathematical personality. There are chapters on the colouring of graphs, on extremal graph theory, on systems of sets, on block designs, on tournaments, on information theory and on random objects; in each there is food for thought for years to come.

There is no sample from the important work of Erdős with Rado and Hajnal on the partition calculus, but this work is to be the subject of an independent book. There is also reference to another forthcoming book, by Erdős and Spencer (the editor) on probabilistic methods in combinatorics; these play an important part in many of the papers and lead to some remarkable existence theorems. Erdős's ability to grasp the essentials of a subject, or a theorem, and to apply them in other contexts is well illustrated by the striking use he has made of probabilistic arguments in many fields.

Each chapter is prefaced by a short editorial commentary but there are few textual corrections and there could have been more information about the subsequent history of some of the problems that Erdős has proposed over the years; there is the occasional reference, but sometimes only to the author's name. At the end of the book is an invaluable bibliography of all of Erdős's papers up to the present—some 600 papers in all; it is quite clear what his target should be for his 100th birthday!

H. HALBERSTAM

Gas chromatography

Techniques of Combined Gas Chromatography Mass Spectrometry: Applications in Organic Analysis. By William McFadden. Pp. 463. (Wiley-Interscience: New York and London, 1973.) n.p.

Gas Chromatography in Inorganics and Organometallics. By G. Guiochon and C. Pommier. Translated by STS, Inc., Ann Arbor, Michigan. Pp. viii+332. (Ann Arbor, Michigan; John Wiley; Chichester, December 73.) £10.

New Developments in Gas Chromatography. Edited by Howard Purnell. Pp. vii+408. (Advances in Analytical Chemistry and Instrumentation: vol 11.) (Wiley: New York and London, 1973.) n.p.

THE combination of gas chromatography and mass spectrometry is the most powerful tool yet devised in the

analytical chemistry of volatilisable organic materials, and there has been a need for a practically oriented book which would serve as a guide to the two techniques and their interrelation. McFadden's book seems to meet this need admirably. Both mass spectrometry and gas chromatography are introduced satisfactorily, but the technical emphasis is clearly stronger in the former so that the book will be most useful to those with some background and experience in gas chromatography. The interfacing of the two techniques, one vacuum and one atmospheric but otherwise beautifully compatible, is discussed in depth together with the methodology of operating them together and the role of computers. The main part of the book is based on a regular course of lectures and this seems to have given it an extra coherence and clarity. In a happy choice of method, the last chapter is a series of some sixteen short contributions by various authors each covering a different field of application or specialised technique.

The second book is essentially a translation of the excellent French text of Guiochon and Pommier on "Gas Chromatography in Inorganic Chemistry". Though the applications of gas chromatography in organic chemistry have been legion, those in inorganic chemistry are much more restricted. The whole field and its problems and successes are most clearly reviewed and considered in this work. After a short introduction to gas chromatography itself there follow discussions of analytical separations achieved in the fields of inorganic gases, halogens and non-metallic halides, metals and metal halides, hydrides, organometallic compounds, metal chelates and isotopes. Finally, there is a brief account of non-analytical applications such as the measurement of thermodynamic parameters and preparative chromatography. It is a pity that the translation is rather uninspired and the proof reading somewhat slipshod.

Purnell's *New Developments* is an interesting collection of seven specialist articles, most of which lie outside the realm of analytical chemistry suggested both by the title of the series with which this book is associated and indeed by the most common applications of the technique. The authority and personal emphasis which characterise most of the articles reflect the fact that they are written by recognised experts on their own fields. The first is a review of the many forensic applications of gas chromatography. The second provides an admirably clear introduction to the jargon and use of digital computers. Four articles then concentrate on the study of various processes of physicochemical interest by

gas-chromatographic methods; namely phase changes which occur in materials used as stationary phases, polymer structures and interactions (by inverse gas chromatography), the determination of the formation constants of complexes, and the kinetics of chemical reactions (by using the chromatographic column as a reactor). Finally, there is a timely, well balanced and dispassionate account of gas chromatography on the production (as distinct from the preparative) scale. This particular package may seem at first sight to have a rather narrow appeal, but I found it both satisfying and curiously homogeneous: it certainly provides a stimulating and very up to date introduction to the wider aspects of gas chromatography.

C. S. G. PHILLIPS

Physics with computers

Computational Physics. By David Potter. Pp. xi+384. (Wiley-Interscience: London and New York, October 1973.) £5.50 cloth; £2.50 paper.

THE widespread use of computers in problems of physical science is enabling investigations to be carried out which are not subject to some of the restrictions of mathematical analysis. As a consequence some, who have not given adequate attention to the difficulties of interpreting the voluminous output of computers, have consigned analysis to the back room. It is therefore pleasant to welcome a book which shows that good analysis and sound physical thinking must go hand in hand with numerical technique if computational results are to have any validity and reliability. The introduction, at least, should be compulsory reading for any physical scientist before he embarks on an extensive and expensive computer program. He will also find much that is well worth reading in the rest of the book but he must not expect to find a discussion of every problem of interest to him.

Although the book is called *Computational Physics* it really deals only with difference methods. There is no mention of finite elements or integral equations at all. Numerical analysis, as such, is confined to three chapters so that some topics are discussed more cursorily than desirable. Some places where fuller treatment is required are: interpolation and its difficulties; the fast Fourier transform; Poisson's equation when the boundary condition is not of Dirichlet type; eigenvalue methods. In general, the reader seeking the whys and wherefores of numerical techniques for ordinary and partial differential equations will have to consult other texts such as those of Lambert and Mitchell.

The book is not really suitable for

undergraduate teaching, partly because there are no exercises and partly because so many ideas creep in unannounced; for example, spectral radius, tensor inner product notation, Poisson brackets, sodium chloride mesh (note also that the definition of spectral norm is unsatisfactory).

Nevertheless, postgraduate workers will find this an extremely useful book to have for several reasons. It collects together material on numerical attacks which is not readily accessible elsewhere and provides an extensive bibliography covering many fields of application. Throughout there is careful discussion of the physical and mathematical approximations undertaken in reaching a stage where the computer has a reasonable chance of supplying a satisfactory answer. The relative merits of alternative approaches are also described.

Chapters 5 and 6 are devoted to the motion of numbers of particles, with and without field averaging, as in the collisionless case in plasmas and astrophysics while compressible hydrodynamics is an example of collisions. Long range quantum forces appear in chapter 7. The distribution function approach and Vlasov's equation occupy chapter 8. Chapter 9, dealing with hydrodynamics is the longest. It shows how the particle-in-cell method can display the development of Helmholtz instability and the creation of a von Karman vortex street; the marker technique for moving surfaces and breaking waves is also given (though the absence of Zabusky's work on the non-linear interaction of waves is a notable omission).

The complex nature of compressible flow is clearly brought out, and, in chapter 10, the related problems of magnetohydrodynamics are emphasised. Evidently, some new good ideas are going to be necessary before the computer can cope adequately with the diverse phenomena of shock waves and other large amplitude disturbances.

Well printed, the book is good value and will be appreciated by researchers.

D. S. JONES

Life in glacial Mexico

Das Mexiko-Projekt der deutschen Forschungsgemeinschaft. 6: Geologische und paläontologische Untersuchungen im Valsequillo bei Puebla, Mexiko. By E. W. Guenther, with H. Bunde and G. Nobis. Pp. 177; 14 plates. (F. Steiner Verlag: Wiesbaden, 1973.) DM. 69.

THE Mexico project of the German Research Association is a regional study of the Puebla-Tlaxcala Basin, with man in his local environment, from the Stone Age to the present, as its central theme. The present work concerns the geology and palaeontology of a small area some 10 km south of the City of Puebla.

Bird's eye view

PHOTO-mosaic of the west coast of Schleswig-Holstein. Taken from *The Earth from Space* by J. Bodechtal and H.-G. Gierloff-Emden, translated by H. Mayhew and L. Evans (David and Charles: Newton Abbott, January 1974; £6.50), this is in fact one of the few illustrations in the book not taken from space. The importance of this kind of mosaic is that a series of photographs on a scale of about 1:20,000 can be combined and reduced in size to give a picture with scale corresponding to satellite photographs; it is just possible to bridge the gap between satellite photographs and ordinary aerial photography.

Valsequillo owes its importance, in this context, to finds of undoubted stone implements in association with remains of extinct mammals, at horizons which though still not securely dated, suggest dates of the order of 40-50 thousand years BP. If this is the case they might be of an age some 10 thousand years earlier than any other evidence for the presence of early man in the New World. The present work contributes new facts and considered judgments of their implications to the basic disciplines of geology and palaeontology, on which any final decision as to the date of the human occupation must ultimately rest.

The palaeontological finds, apart from those of equids and elephants, have been dealt with elsewhere by other authors, but their results are summarised by Guenther in the introduction. Carnivores represented are coyote, dire wolf, a sabre-toothed cat and a very large bear, *Arctodus simus*. One fragment of a tapir is the only perissodactyl other than the horses. Remains of a peccary, *Platygonus cf. compressus*, were found in several examples. Camelids were not uncommon and two species of *Camelops* and one *Tanu-*

The Solar Chromosphere

R. J. BRAY AND
R. E. LOUGHHEAD

International Astrophysics Series

February 1974: 404 pages: 55 line illustrations and 40 pages of plates: 0 412 10730 9: hardback: £9.00

The subject of the solar chromosphere is central to modern developments in both solar physics and astrophysics generally, not least because modern observations suggest close links with such diverse phenomena as the solar wind and the deep-lying convection zone responsible for supergranulation.

This book forms a comprehensive discussion on the solar chromosphere and the many illustrations and tables give the reader easy access to modern quantitative data on the subject. The emphasis throughout is placed on the quiet chromosphere although a short chapter has been included on the active region.

Experimental Physics for Students

R. WHITTLE AND
J. YARWOOD

December 1973: 370 pages: numerous illustrations: 0 412 09770 2: hardback: £4.95

This textbook describes in detail about 135 experiments suitable for undergraduate students. All the experiments described have been carried out in the laboratory and in all cases the necessary theoretical background is outlined before full descriptions are given of the procedure. In many instances, typical experimental results are provided and the analysis of the significance of these results is discussed.

A complete catalogue or further information on these titles, together with a list of stockists, is available from the publishers on request.

CHAPMAN & HALL,
11 New Fetter Lane,
London EC4P 4EE

polama are indicated. Of pronghorn antelopes, there was a small *Breameryx* and two larger species, probably both *Tetrameryx*. Several finds of *Bison* sp., including a fine skull with horn-cores, are compared with known New World species. Edentates included a large armadillo (*Holmesina*), a single ossicle of a glyptodont, *Brachyostreon*, and the flattened pelvis of a ground-sloth, *Nothrotherium*.

Most of the remains came from the Middle (see below) fossiliferous horizon, perhaps datable to an interstadial of the Last Glaciation corresponding with the European Paudorf, 28,000–25,000 years BP.

H. Bunde gives topographical and geological maps marking the positions of more than 190 exposures visited, from which some 1,200 samples of loose sediments and 80 hard-rock samples were collected. Pains-taking heavy-mineral analyses of these enabled him to divide the late Tertiary to Recent deposits into four main zones, according to their dominant heavy-mineral species: Pliocene, an Mg-hornblende zone; Pleistocene, a thick Fe-hornblende zone, interrupted near its summit by pumice and ash falls with dominant olivine, from a local vent. This included the lower fossiliferous deposits. The middle fossiliferous horizon lay near the base of the succeeding hypersthene zone, to which a Wisconsin date is attributed. Above, including the uppermost fossil beds, was a zone with dominant biotite, of Late Glacial and Postglacial date. The accompanying mineral spectra make these subdivisions perfectly convincing, and on their evidence were based correlations leading to a composite stratigraphical column in the above sense.

There is a clear potential practical value of this conclusion, for correlating generally very varied and only locally occurring fine-grained strata of differing appearance, often more or less weathered or redeposited by wind or water and in no other way readily assignable to their relative positions in a sequence. It may well have important results in the archaeological field when applied to deposits containing mammalian fossils and artifacts.

G. Nobis's study of the horse teeth recognised three groups: two larger species with primitive 'zebroid' features, the first of which might be assigned to *Equus* (*Hesperohippus*) *mexicanus*, the second remaining indeterminate. A third, smaller, species resembles *Equus conversidens* Owen, an asinoid parallel with the Eurasiatic *E. hydruntinus*. The specimens in question are well illustrated in two plates.

E. W. Guenther's contribution is an exhaustive study, with numerous graphs and scatter diagrams, illustrating the

morphological and metrical characters of a collection of between 40 and 50 elephant teeth. He compares them with others found in Mexico and with the well known rich collections from Süssengborn (*P. trogontherii*) and Vogelherd (*M. primigenius*). He concludes that most represent *M. columbi*, about 10 of them *M. imperator* and only two, without provenance, *M. primigenius*. To these he adds a late, dwarf, species, hitherto undescribed, which he calls "*M. primigenius diminutivus* var. *mexicana*". The upshot is that practically all the elephants are of interstadial or interglacial forms, as the stratigraphy would suggest. The study is of methodological importance and introduces a number of new techniques for the measurement and graphical presentation of such material.

In all, this is an important publication, which should interest not only Americanists, but geologists and palaeo-anthropologists in general. The price, however, may restrict its availability to libraries only.

I. W. CORNWALL

Problems with light

Problems in Optics. By M. Rousseau and J. P. Mathieu. Translated by J. Warren Blaker. Pp. ix+366. (International Series of Monographs in Natural Philosophy Volume 52.) (Pergamon: Oxford and New York, 1973.)

THIS collection of problems in optics includes not only the classical aspects of physical optics, such as diffraction, interference, polarisation and dispersion but also electromagnetic waves, atomic and molecular spectroscopy and quantum mechanics. Although the problems set are keyed to the complementary text, *Optics* by Mathieu, in the same series, it is not really necessary to have access to this book to make good use of the present volume. The approach adopted is to set, usually three, closely related problems and to follow these by detailed solutions, each of which begins with a summary of the relevant physics required. There are many numerical computations so that the student is adequately drilled in the manipulation of units (MKSA rationalised units are used throughout) and is also given practice in estimating the orders of magnitude of the various quantities involved. The book can be fairly said to have met the two principal objectives of its authors, to teach the principles of optics and to teach the methods of problem solving. The text is well printed and the diagrams are clear and easily understood. The translation from the original French is excellent and reads well. There is good consistency in the use of symbols and constants with a convenient summary at the beginning.

With the renaissance in optics brought about by the developments in laser physics and space research, this book has come at an opportune time and should be particularly valuable to research workers in solving real problems, as well as to academic staff, who have to set examination questions, and to students who have to answer them. I have already found it invaluable in helping tutorial students to solve honours degree examination problems. To sum up, this is an excellent book and I strongly recommend it.

D. J. BRADLEY

Where the oil is

Oilfields of the World: Geology and Geography. By E. N. Tiritsoo. Pp. viii+376. (Scientific: Beaconsfield, 1973.) £8.50.

THE subtitle of this book, *Geology and Geography*, is an unduly large claim for a volume of only 376 pages. Nevertheless it is a useful and up to date reference book, the more valuable for its appearance at this critical time in the history of exploration of natural hydrocarbons.

The book begins with an introduction on the history, nature and occurrence of oilfields. Much of this is elementary, but it has the merit of defining and explaining many of the terms peculiar to the petroleum industry, definitions often not readily available to the non-specialist (for example 'naphtha', 'middle distillate', the niceties of varying reservoir type and of different ways of quoting reserves figures).

The greater part of the book is occupied by a catalogue of the world's oilfields. This is somewhat uneven in emphasis, with relatively modest space given to the Middle East in proportion to the bulk of its reserves (a tenth of the space for half the world's oil), but it has the particular merit of giving generous treatment of areas on which information is much more difficult to obtain—notably Eastern Europe, the Soviet Union and Eastern Asia. The treatment of the United States is perhaps disproportionately long (twice the space allotted to the Middle East) but the enormous number of small fields and the overall complexity would make any shorter treatment very difficult to arrange.

The main disappointment is that the treatment of geology is scanty in the extreme. The age and nature of reservoir beds is quoted for most of the oilfields described, but there are no stratigraphic columns, no structural maps, and no structural sections except for the generalised textbook diagrams in the introduction. With a great wealth of available material to draw upon in the world's literature, this seems a

major opportunity lost, and the brief descriptions included in the text do not go very far to fill the lacuna. The net effect has been the production of a highly informative geography of petroleum sources, but it is a catalogue rather than a stimulus to ideas.

Participants in the recent Royal Society symposium on "Energy in the 1980s" may be interested to see that units are given uniformly in barrels per day or barrels per annum. There is certainly merit in uniformity, and the author has successfully avoided the pitfalls of different kinds of tons and of (for example) the three different official conversion factors for "coal equivalents". Nevertheless it would have been useful to have had summary figures given in energy terms, in joules or 'Q', for those users of the book who are attempting to relate mineral oil to the statistics of other sources of world energy.

The book ends with a chapter on reserves, requirements and future supply, in which the potential for expansion of conventional sources, and the alternatives provided by tar sands and oil shales are discussed. Dr Tiritsoo echoed the warnings of Warman in the United Kingdom, Halbouty, and others in the United States, that the rate of discovery of giant oilfields (the significant contributors to the world's reserves) has fallen sharply since 1960, and—writing before the current potential crisis—he concluded by underlining the decision of Kuwait and Iraq, made in 1972, to curtail production against future requirements with the apposite quotation from the Rubaiyat:

"I often wonder what the Vintners
buy
One half so precious as the stuff
they sell".

The industry has not been devoid of people clear-sighted enough to envisage the present crisis; it is a pity that governments have not always been equally prescient.

P. E. KENT

Background to a battle

The Quantum Theory of Light. By R. Loudon. (Clarendon: Oxford; Oxford University: London, November 1973.) £7.50.

THE quantum theory of electromagnetic radiation has once again become the subject of lively discussion, thanks to the advances in the field of laser physics. These advances have made easily available sources of radiation with coherence and intensity characteristics completely different from those used by experimenters in the past and have produced new controversies over the specific application of quantisation to radiation fields.

But before it is possible to enter the quite heated battles surrounding this subject, it is necessary to obtain a grounding in the basic theoretical concepts involved in the discussion of the interaction of radiation with matter. Dr Loudon's book provides an excellent beginning to such a grounding, at a level suitable for graduate students, or good finals-year undergraduates.

Beginning with a review of classical radiation theory as applied to emission and absorption processes, the classical theory of optical coherence is briefly discussed. Quantisation of the radiation field is introduced, together with the properties of photon phase and number operators. This leads to a discussion of photon absorption and emission in terms of quantised field theory and a general discussion of photon optics including a brief section on laser theory and nonlinear optics.

To briefly single out only two chapters: the discussion of classical coherence theory is very well done and the notation carefully chosen so that an easy transition to the quantised approach can be made. Similarly, the discussion of photon optics provides an excellent introduction to the subject.

The general production of the book is excellent. The salting of the text with problems, which might be thought inappropriate at this level, seems an excellent idea and the references at the end of each chapter are comprehensive.

Although I have definite reservations on the blanket use of quantum field theory in optics, this book can be highly recommended to students in the field.

D. G. C. JONES

Unimolecular reactions

Theory of Unimolecular Reactions. By Wendell Forst. Pp. xv+445. (Physical Chemistry: vol. 30.) (Academic (Harcourt Brace Jovanovich): New York and London, November 1973.) \$29.50.

ANYBODY who has had a more than superficial interest in the theory of unimolecular reactions will be familiar with the names of Wendell Forst and O. K. Rice, who contributes the foreword. The latter's encouragement and stimulus to many research workers in this field, including Wendell Forst, should not pass without mention.

The volume is divided into two parts, the first of which deals with the general concept of the unimolecular process, the definition of such basic quantities as average rate and the basic assumptions involved. Slater theory is mentioned only in passing and to place its assumptions in correct perspective. There follows a discussion of intramolecular energy transfer and the assumption of energy randomisation. Chapter 4 considers the statistical cal-

ulation of the unimolecular rate with respect to phase space in both classical and quantum-mechanical formats; pertinent degrees of freedom are thoroughly discussed, due attention being drawn to the necessary restrictions implied by conservation theorems. As might be anticipated, a lengthy and excellent chapter on energy-level densities is included and should enable the reader to utilise the various approaches in actual calculations.

Part 2 divides itself naturally, through the average energy of the excited species, into a discussion of thermal reactions, chemical activation systems (including photoactivation) and, most welcome, a detailed consideration of the fragmentation of highly excited molecules and ions. These make excellent reading indeed, and the detailed analysis of rotational effects, where appropriate, is certainly worthy of comment.

References are given at the end of each chapter and are both extensive and up to date; a glossary of the symbols used, together with their clear definitions (always welcome in this field), is given as well as an author and subject index.

The author rightly appeals in an appendix, for the more extensive use of the results of the steepest descents method of calculating energy-level densities. A simple basic programme is given as further encouragement.

I found my task of reviewing this book both rewarding and enjoyable, and even at a price in excess of twelve pounds, no one with any pretensions to interest in this field can afford to be without a copy.

W. J. ORVILLE-THOMAS

Arctic circle

Arctic Geology. (Proceedings of the Second International Symposium on Arctic Geology, held February 1-4, 1971 at San Francisco.) Edited by Max G. Pitcher. Pp. xvii+747. (American Association of Petroleum Geologists: Tulsa, Oklahoma, 1973.) \$30.

THERE is a certain scale of geological phenomenon that may suddenly come into focus when the appropriate mixture of specialists come together at a symposium. The formula works particularly well when the solution of a geological problem requires knowledge of the geology of a number of countries. This book contains some seventy papers read at a symposium on Arctic geology held early in 1971. To my mind the result is particularly rewarding in two ways. The specialist will find discussions of the geology of Alaska, of Arctic Canada and the Soviet Union, of the Arctic ocean, the North Atlantic and the North-

ern arc of the circum-Pacific fold belts together with first class reviews of various stages in their geological history.

But above this and of more importance to the science as a whole the symposium succeeded in illuminating the geology and the economic potential of the succession of sedimentary basins which overlie the Precambrian blocks clustered around the Arctic Ocean. By the end of the century a quarter of the world's production of hydrocarbons may come from the Arctic. The ring of Precambrian blocks which underlie Canada, Greenland, Northern Europe, north-west and north-east Siberia have separated and come together in a complicated fashion during the past 500 million years. The mountains of Scotland and Scandinavia, the Appalachians, the Urals, the island arcs and the mountain chains around the northern Pacific and the North Atlantic itself are direct results of these movements. Their history is traced out in this book, as is the history of the sedimentary basins which are so important as potential or actual sources of petroleum. This book can be recommended as providing an excellent synthesis of a region likely to become of ever increasing importance in the remainder of this century.

JOHN SUTTON

Impurities have virtues

Deep Impurities in Semiconductors. By A. G. Milnes. Pp. xviii+526. (Wiley-Interscience: New York and London, 1973.) n.p.

STUDIES of the electrical properties of semiconductor crystals containing impurities fall into at least two distinct categories. The first is concerned with the determination of the position and nature of localised electronic states due to specific impurities, and perhaps the accounting for these properties in terms of theoretical models. The second category relates to the electrical behaviour of such material under non-equilibrium conditions and to the properties of junction structures. It is important to recognise that work in these two areas is in general carried out by different groups of research workers and consequently the bridge between them is often quite tenuous.

The present volume aims to be complete in this context, although analyses of defects produced by irradiation damage are explicitly omitted. The theory of localised energy levels is discussed briefly in chapter 1, which is followed by reviews of data for silicon, germanium, gallium arsenide, gallium phosphide and other III-V compound crystals in chapters 2 and 3. The latter chapters read very much as a catalogue,

but are nevertheless valuable because of the large number of references cited. There is then a marked change in style in chapters 4, 5 and 6, which deal with theories of steady state statistics of deep impurities, trapping and recombination. Apart from a few examples, of which gold doped silicon is prominent, the deep levels are not considered in relation to particular systems. The emphasis becomes more practical in the following chapters with discussions of photoconductivity, recombination and trapping in junctions, thermally stimulated currents and techniques for measuring lifetimes.

The contents of the remaining four chapters are of considerably more interest. It is shown in some detail how the presence of deep impurities can lead to a negative differential resistance, and oscillatory effects are discussed at length. The relevance of the final chapter on conductivity by hopping processes to deep impurities is not too clear, as is pointed out by the author in the very final paragraph.

An overall impression gained from this book is that the difficulties referred to in the opening paragraph of this review have not yet been overcome, although of course this in no way reflects adversely on the text. A second impression is that the author has given prominence to the beneficial aspects of deep impurities, citing the value of infrared detectors and possible future uses of oscillatory phenomena. Adverse effects such as the quenching of luminescence, reduction in carrier mobilities and lifetimes would be regarded by many as being equally if not more important. Finally it should be noted that the very large bibliography containing nearly 1,900 items should be invaluable to workers in this field.

R. C. NEWMAN

Ancient climates studied

Climatic Fluctuations of the Ice Age. By Burekhard Frenzel. Translated from the German by A. E. M. Nairn. Pp. xxiv+306. (Case Western Reserve University: Cleveland and London, November 1973.) \$22.50.

THE world's climate is not only changing, but changing on a timescale rapid enough to affect present day economic planning. Interest is growing in the problems of climatic change in general, and in such spectacular examples as ice ages in particular. So the arrival of this translation of Frenzel's 1967 German language study of the most recent ice age is particularly well timed.

The book concentrates upon facts, rather than hypotheses to explain the factual variations, and thus provides a useful reference for anyone wishing to

PINGOS in East Greenland. Squeezed between the permafrost layer below and the winter freezing layer above, the water-bearing horizon in some Arctic regions can be subjected to pressures of 50 atmospheres. This causes hillocks to form, up to 40 m high and 100 to 200 m in diameter; when the ice core of the pingo eventually melts, a crater-like depression is left, and these depressions may remain as a visible record of a period of severe climate.

jump off into the unknown with their own hypotheses. Climatic fluctuations during the Pleistocene undoubtedly have their origins in the same changes in the global pattern of circulation, or of input of solar radiation, that cause the climate to change today—but of course, it is not yet clear exactly what those changes are. This well planned and thorough discussion of the methods by which ancient climates can be studied, and what comes out of those studies, will be particularly useful to those people from many disciplines who are turning part, at least, of their attention to these questions; not least among the useful features of the book is the comprehensive bibliography.

JOHN GRIBBIN

How many worlds?

The Many-Worlds Interpretation of Quantum Mechanics. Edited by Bryce S. DeWitt and Neill Graham. Pp. viii+252. (Princeton University: Princeton, November 1973.) \$12.50.

THE 'many-worlds' interpretation is surely the most exotic product of the endless struggle to understand quantum mechanics. To avoid any suggestion of the infamous 'reduction of the wave packet' it is supposed that not only does the wave function not reduce, during measurement, but that physical reality multiplies. On each occasion not just one but all possible measurement results are realised! To accommodate them all an increasingly multiple world is required, one 'branch world' for each

possible sequence of results. It is supposed that, in each branch, objects (including people) interact with (and are conscious of) others in the same branch only. So we are not aware of the many worlds that we do not inhabit; the people, often very very like us, living in those other worlds, are other people.

If you have not personally found the time to grapple seriously with the puzzles of quantum mechanics it can hardly be intelligible to you that physicists might be driven to such lengths. And even if you have found the time, you may wonder in what way such a conception is superior to the de Broglie-Bohm pilot wave theory; there also the wave never reduces, but only one of the many possible physical configurations is realised, and evolves in time in a way consistent with quantum mechanical probabilities. My opinion is that the pilot wave provides a simpler and more economical solution of the problems motivating both approaches, and is quite superior in requiring neither any arbitrary classification of physical processes into 'measurements' and others, nor any arbitrary division of the world into 'systems' and 'apparatus'. I have to add, however, that my understanding of the pilot wave theory was much enhanced by some aspects of the 'many world' picture, in particular its emphasis on memory states. Moreover it is the very clarity and precision of the pilot wave theory which puts in prominence the particular difficulty concerning locality. But this is not the place to develop that theme.

The book under review is mainly a collection of preprints: the original 1957 paper of Everett, a contemporary assessment of it by Wheeler, later expositions by de Witt (1969 and 1970), and a later rediscovery of similar ideas about correlations in memory states by Cooper and Van Vechten (1969). Cooper and Van Vechten explicitly invoke 'irreversibility' to distinguish some physical processes from others as 'measurements', so exhibiting more prominently a basic vagueness of the approach. They also explicitly dissociate themselves, in a footnote added in 1972, from the many worlds concept; they see no reason for more than one of all the possible worlds actually to 'come to pass'. This puts them still closer to de Broglie and Bohm, but even they do not recognise this affinity.

In addition there are two hitherto unpublished papers. One is an alternative account by Everett himself, written apparently before the well known paper mentioned above. Although it does not add anything (it seems to me) on central points it contains some interesting auxiliary material, including in particular a discussion of various measures of uncertainty, and some comments on other approaches to quantum mechan-

ics. Here the de Broglie-Bohm picture is mentioned; Everett thinks his own picture is simpler. The other new paper is by Neill Graham. He is concerned about the arbitrariness of the measure (actually the quantum mechanical norm) invoked to weight the various branch worlds. He argues that with sufficiently complicated (ergodic) apparatus simple equal weighting of different branches is practically equivalent. In the form actually given the argument supposes the multiple world divided into discrete branches, classified by the discrete eigenvalues of some privileged 'observables'. That suitable operators with discrete eigenvalues can be considered in the neat world of academic quantum mechanical measurement theory is clear. The messy real world, in which each piece of measuring equipment is immersed in a particle and radiation bath from which it is only vaguely separated (on the microscopic scale) may be another problem.

The search for a satisfactory interpretation of quantum mechanics is likely to continue for a long time among many, rightly or wrongly, unsatisfied people. The many worlds interpretation, its tenability or untenability, and the sidelights it throws on other schemes, will continue to be discussed. For participants in that discussion this will be a useful book to have.

J. S. BELL

Quantum textbook

Fields and Particles: An Introduction to Electromagnetic Wave Phenomena and Quantum Physics. By Francis Bitter and Heinrich A. Medicus. Pp. xiii+688. (American Elsevier: New York, London and Amsterdam, 1973.) Dfl. 52; \$20.

THIS is an ambitious book which takes the reader from electromagnetism through a wide variety of wave phenomena to a discussion of the symmetries of elementary particles. For so large a book the price is very reasonable, and at its best its merits are sufficient for the buyer to feel he has got his money's worth. Nevertheless there are notable imperfections which cause me to hesitate before recommending it as the basis of a major course at, say, first or second year level in an English university.

To begin with a few minor examples, as typical of the rather numerous blemishes to be eliminated in the next edition: it is implied (page 199) that as a wave packet spreads by dispersion, the frequency range in its composition gets less; the discussion of Poynting's vector (page 627) involves a mathematical oversimplification which carries the corollary that all lines of force are straight; the phase-amplitude diagram

An Introduction to Conservation of Orbital Symmetry

A programmed Text
A J Bellamy

This book provides an introduction to the conservation of orbital symmetry. The reader will find that his understanding of the concepts of the subject and his confidence in using them are both developed rapidly as he works through the programmed problems. £1.50

General Inorganic Chemistry

Second Edition
J A Duffy

This second edition of General Inorganic Chemistry is for students taking chemistry to General B. Sc. and equivalent levels. It also provides a sound introduction for those who intend to read for an honours degree. £2.50

X-rays in Atomic and Nuclear Physics

Norman A Dyson

An account drawn from several different branches of physics, of the physical aspects of X-ray production. The book will prove valuable for final year undergraduate and postgraduate students using X-ray techniques in such fields as crystallography or materials testing who need a text on the basic physical processes of X-ray production. £7.50

Freshwater Ecology

2nd Edition
T T Macan

A Review of the first edition: "A much needed book, written by a foremost authority on the subject. . . this book will be welcomed in every university zoology department and in sixth forms. . . No ecologist can afford to miss it"

British Book News

Statistical Tables for Biological, Agricultural & Medical Research

Sixth Edition
Fisher and Yates

This book of statistical tables, first published in 1938 by Oliver & Boyd, is now being reprinted by Longman. This is the Sixth Edition (1963) with minor corrections. It has long been regarded as a standard work essential for all statisticians and biometricians, especially those concerned with investigations on highly variable material. £2.50

Longman
1724 - 1974

(page 90), so essential for an appreciation of diffraction at this level (and for that matter at a much higher level), is thrown in far too peremptorily for a student whose experience of complex numbers is as rudimentary as seems to be assumed; Fourier analysis (page 61) is left rather as a mystery, when a few pictures could have brought the mathematics to life.

But even with these faults corrected, I should still have doubts, and not only those of a partisan of the solid state who wonders whether it is still so obviously the overriding goal of physics to press on single-mindedly in the pursuit of the fundamental laws. It is not just this, but a feeling (of which some of the specific points just cited are evidence) that the book does not encourage the student to grow as he learns. There are some comparatively elementary texts (Born's *Atomic Physics* springs to mind) to which one can turn again and again, after a spell of more advanced work, to find that the heart of the matter is there; the learner's difficulties are appreciated and overcome without condescension. Such books the serious student will cherish all his life, but this I fear is not one of them. If he comes back to it he will feel that he was talked down to just a little, that the book explained to him little more than what it set out to explain, without any of the shafts of illumination that a great master can give—cannot but give—along the road. In short, it has the makings of a sound textbook; it could not be called, in the highest sense, a work of scholarship. And this a pity, for our best students deserve the best we can offer.

A. B. PIPPARD

Spinning electrons

Electron Spin Resonance: Theory and Applications. By N. M. Atherton. Pp. x + 438. (Ellis Horwood, distributed by Wiley: Chichester; Halsted (Wiley): New York, November 1973.) £11.50.

THE theory and techniques of electron spin resonance have now been developed for almost thirty years, and yet the subject still has its growth points, and is still attracting large numbers of research students. The author of this text has seen a real need to provide a basic reference text for new (and existing) workers in this field. Most books on this subject require frequent recourse to other sources, but in this case most aspects of the theory are developed from a sufficiently elementary level to make the text particularly useful to postgraduate physicists and chemists. In that it deals essentially with the theoretical background to the subject, the text forms a useful companion to other recent publications on experi-

mental techniques cited in the bibliography.

The first two chapters of the book deal essentially with introductory aspects of the subject, and form a sound basis from which the subject can be developed. They are followed by two chapters dealing principally with most aspects of the ESR spectroscopy of radicals in solution and trapped in solids. Chapters 6 and 8 deal with the theory of transition metal complexes and with the basic theory of the g -tensor and are followed by two comprehensive chapters on relaxation and lineshape theories. The interpretations of experimental parameters such as g values and hyperfine splittings for simple systems are developed extensively. The sections concerned primarily with transition metal ions tend to stand out in contrast to other sections in that the theory is not developed from quite the same basic level as in the earlier chapters: an inevitable consequence when trying to cover such an extensive subject in so short a space. The problem is helped however, by an excellent bibliography. The final chapters are concerned with two particular aspects of the subject: double resonance and gas phase electron resonance.

The whole range of material covered by the text relies considerably on a basic understanding of quantum mechanics. Though the level of knowledge required is beyond many undergraduate physics and chemistry courses it would require very little effort for most postgraduate students to achieve the necessary standard. The text might have benefited from a brief appendix outlining the principal techniques required such as elementary matrix methods, perturbation theory and some aspects of angular momentum theory. The majority of the topics are developed from an elementary level but unfortunately, although perhaps inevitably, the discussion ceases before many of the interesting examples. Many of the topics treated could have benefited from a few more illustrative numerical examples.

In conclusion I should say that the text forms a very worthwhile contribution which will certainly be a standard requirement for most laboratories working in this field. Many workers in electron resonance spectroscopy have long felt the need for a work of this kind, and I hope that the publishers will consider producing a cheaper paperback edition. The author has undoubtedly achieved his aim described in the preface, namely, to produce a book which will prepare people to read the electron spin resonance literature and that would be useful for a number of years.

E. F. SLADE

BIOLOGICAL SCIENCES

Promoting plants

Phytochemistry: the Process and Products of Photosynthesis. Edited by L. P. Miller. Vol. 1, pp. xiv+410; vol. 2, pp. xiv+445. (Van Nostrand Reinhold: New York and London, June 1973.) Vol. 1, £11.25; vol. 2, £12.25.

The Biochemistry of Green Plants. By D. W. Krogmann. Pp. xiv+239. (Prentice-Hall: Englewood Cliffs, October 1973.) £11.95.

PLANT biochemistry has always been a Cinderella subject, and a Cinderella who has not yet met her fairy godmother. Due principally to the attitude of mind that M. D. Kamen has referred to as "mammalian chauvinism", the study of the biochemistry of plant processes has to date been an undeservedly neglected field. Even the rawest biochemistry undergraduate appreciates that the fixation of atmospheric CO₂ by green plants utilising solar energy is the most important chemical process in the biosphere; nevertheless as he pursues his biochemical career, he gradually becomes indoctrinated into the view that those processes which occur in animal cells are of paramount importance and that the study of plant processes is not a suitable field in which to carve a career.

Fortunately, there are signs that this trend is due to be reversed. The consuming requirement for increased global food supplies is bound ultimately to direct attention towards the mechanisms of plant growth and productivity, which surely can only be properly understood at the biochemical level. Both of the books under review attempt in their own completely different way to act as fairy godmothers for plant biochemistry, one by selecting for detailed treatment the currently most fashionable topics within the subject, and the other by dealing exhaustively with the peculiar ability of plants to synthesise substances of fascination for the organic chemist.

In his selective textbook Dr D. W. Krogmann has attempted to show, in terms that an undergraduate can assimilate, the excitement that investigating plant biochemistry can bring. It does not attempt to deal with secondary product biosynthesis, at which plants are adept, but does give intensive coverage of a range of processes which either only occur in plants, or are particularly well illustrated by plants. These include hexose breakdown, nitrate and sulphate reduction, photosynthesis, cell wall biochemistry, fat metabolism, chloroplast development, photomorphogenesis and hormone action. It is undeniable that there is a substantial gap

in the literature which this book attempts to plug. The treatment, however, is rather patchy. The detailed coverage of photosynthesis, hexose metabolism, cell wall synthesis and lipid metabolism is very complete and would be of great assistance to students of plant biochemistry. On the other hand, the book falls down a little in the area of control of metabolism by light and hormones—these, however, are immense subjects in their own right and perhaps the superficial coverage presented here would be considered sufficient by most undergraduates. In any case, the book is a welcome addition to the available literature, not least because it is written in an entertainingly informal style (including verses from Ogden Nash) and yet fearlessly challenges the view that the only really interesting biochemical processes go on in *Escherichia coli* and *H. sapiens* var. HeLa.

The opposite approach is taken by Dr L. P. Miller who has undertaken to edit a three-volume treatise (only the first two volumes of which are yet available for review) on phytochemistry. In contrast with Dr Krogmann's book, the treatise is substance-oriented rather than process-oriented. This will undoubtedly ensure its popularity with organic and natural product chemists, but will probably mitigate against its purchase by genuine plant biochemists of which in any case there are very few. The first volume deals with photosynthesis, photosynthetic pigments and photosynthetic products, namely the various forms of carbohydrates. The second volume covers the various organic metabolites synthesised by plants including amino acids, proteins, purines and pyrimidines, alkaloids, steroids and flavonoids. The standard of coverage, both in comprehensiveness and depth of detail is consistently of the highest order, as would be expected of the very distinguished contributors to both volumes.

The treatise is clearly not intended as an undergraduate text, however, and it is likely to appeal principally to the research worker and university teacher with specialised interests in natural products. The very scale of the production emphasises the enormous amount of purely chemical information that is available on the substances present in green plants and this treatise should help to accelerate the exploitation of plants for the synthesis of rare and valuable chemotherapeutic agents. As a source book, this treatise should be extremely valuable on the shelves of any biochemical library. Neither of these books will, on their own, pull plant biochemistry out of the doldrums, but they

both serve admirably to emphasise the unique and critically important role of plants in the living world. They should be required reading in all biology and biochemistry departments.

H. SMITH

Lithium therapy

Lithium: Its Role in Psychiatric Research and Treatment. Edited by Samuel Gershon and Baron Shopsin. Pp. xi+358. (Plenum: New York and London, 1973.) \$22.50.

THE use of lithium for the treatment and prevention of recurrent mental illness has been the subject of a remarkably vigorous debate. This book presents an intriguing mixture of chapters from clinical psychiatrists using lithium therapy and also from various groups who are pursuing some of the many possible lines of enquiry into the mechanism whereby a simple metal ion can restore abnormal mood to normal and actually prevent future severe mood changes. It would perhaps have been interesting if one chapter in the book had been written by a representative of the English group of psychiatrists who have so forcibly questioned some of the claims made for lithium therapy.

The careful and detailed research by Danish workers is clearly explained by

Proboscis

ADULT female Günther's dik-dik, from *The Ruminant Stomach: Stomach Structure and Feeding Habits of East African Game Ruminants* by R. R. Hofmann. (East African Monographs in Biology vol. 2.) (East African Literature Bureau: Nairobi, 1973.) Boards £10.60; paper £6.50.

Dr Mogen Schou in chapters 10 and 14. Dr Schou of course, has done much to promote this treatment by his patient advocacy of the real and unique clinical benefits of lithium therapy in the affective disorders. I particularly liked Dr Schou's suggestions that clinicians should record dosage in millimoles lithium, and that drug suppliers should indicate the lithium content of their preparations in the same units. His plea that research reports should state the timing of blood taken for lithium analysis in relation to the last oral dosage of lithium salt is also worthy of mention.

As a clinical chemist I would have wanted some extension of the remarks in chapter 14, page 292 on the need for proper control of serum lithium analysis—and in this context cannot resist asking for more details of the method which allows Drs Gershon and Shopsin in chapter 7, page 133 to quote serum lithium concentrations to three decimal places. (This in no way detracts from a useful account of lithium toxicity.)

The opening and closing chapters of the book, by Drs N. S. Kline and R. R. Fieve are especially stimulating and outspoken. I was interested, for example, to be reminded by Dr Kline that lithium has a real historical claim to be among the first of the "psychic energisers" and to read that the very cheapness and availability of lithium salts has made drug houses reluctant to market preparations which may compete with other more complex (and profitable) drugs.

In due course it can be expected that lithium will be superseded by more effective and less toxic substances once the basis of its action on mood is clearly understood. Until that rather distant time comes this volume will be required reading for all of those who wish to improve the treatment of patients suffering severe mood disturbance, by the use of well controlled lithium therapy.

G. S. FELL

Runaway chromosomes

Chromosomes in Human Cancer. By J. Cervenka and L. Koulischer. Pp. viii + 203. (Thomas: Springfield, Ill., July 1973.) \$13.75.

THE stated purpose of this book is to "gather all available information on chromosomes in human tumours with the fervent hope that they might be used as a source of understanding of the seemingly disordered chromosomal constitution in human cancer cells and of the few rules which may be derived from these data". The authors have definitely succeeded in the Sisyphean task of gathering the information. The book will be a precious source for the quick identification of sources. Is it pre-

sumptuous for one who has no clinical qualification to suggest that the fervent hope has not been fulfilled?

The few rules which emerge are commonplaces of the dynamics of cell populations, and indeed of populations in general. These rules derive from first principles of evolutionary genetics (including cytogenetics) and have been experimentally confirmed with unicellular organisms and with cultured somatic cells and transplants of higher organisms including man.

The value of this book does not lie in illuminating the chromosomal mess in tumours. (Incidentally, is enough known about chromosomal variation in normal somatic tissues, especially embryonic?) It lies in the many tables—at least one for each of the major forms of human cancer—which summarises very clearly the published cases in which chromosomal analysis was performed. For this service those engaged in research on tumours, both clinical and experimental, should be grateful to the authors.

G. PONTECORVO

Life is inorganic too

Inorganic Biochemistry. Edited by Gunther L. Eichorn. Vol. 1 pp. xxiv + 1-608; vol. 2 pp. xi + 609-1263. (Elsevier: Amsterdam, London and New York, 1973.) Dfl. 300; \$105.30.

THESE two volumes do not form a book. Rather they hold together thirty-four booklets running from the necessary inorganic chemistry for the understanding of biological roles of metal ions to the description of the metal-containing biological systems themselves. All the important roles of metals are described but most of the booklets are written by an authority largely for other authorities and in a style which precludes a general reader from getting past the first few pages. Many of the chapters are not therefore readable at a sitting and they could as well have appeared in a review journal where the objective is extensive reference rather than intelligent discussion. In fact it is frequently the case that the biological significance of the materials under discussion is lost among the mass of detail on absorption spectra, EPR signals and Mössbauer data. Striking exceptions are the chapters of Nielsens on ion carriers, and by Spiro on phosphate transfer.

I feel that the title of this book should have been 'The Properties of Inorganic Materials found in Biological Systems' for the stress is too far from biological function. The question then arises: is this a book on inorganic biochemistry?

For many years most scientists have looked upon living systems as a growing and self-reproducing organic matrix.

Tropical tree

LEAVES, fruit and flowers of *Hernandia nymphaeifolia*, so called because of the similarity of its leaves to those of the water lily *Nymphaea*. This small tree grows on sea coasts in East Africa, southern Asia and the south Pacific. From *Tree Flora of Malaya* vol. 2, edited by T. C. Whitman for the Forest Department of Malaysia. (Longman: Essex, July 1973.) £12.50.

Such a view is a natural development from the separation of the animal and vegetable from the mineral kingdoms. The distinction, perpetuated in the educational divisions of inorganic and organic chemistry has forced inorganic chemistry more and more toward physical sciences and organic chemistry toward life sciences. Today one knows that this distinction, seen in almost every chemistry journal and in most chemistry courses in schools and universities is wrong-headed. Life has evolved from inorganic materials (generating organic chemistry as it went) and in that evolution has incorporated every facet of inorganic chemistry which was profitable to it. This book clearly proves this point. The only reason for using a title such as *Inorganic Biochemistry* is to get away from the implied title 'Organic Biochemistry' every time an inorganic chemist reads 'Biochemistry'. In other words Avis quite rightly wants a share of Hertz's business: car renting, and the study of biology by chemists, is not a monopoly activity. What then is the inorganic part of biology?

The roles of inorganic materials can readily be separated into the functions of bulk structural units, such as shells and bones, control elements, such as energy stores in concentration gradients, and catalyst centres. What feel does this

book give of these different biological topics?

The great structural role of silica, calcium carbonate, and calcium phosphates is not described. The nature of the nerve pulse, of the triggering of muscle contraction, of hormone release, of coagulation, of almost what you will as far as (inorganic) control over action is concerned receives scant mention with one notable exception. The editor has made it his speciality to deal with the interaction of metal cations with the polymers of translation and transcription, RNA and DNA. Yet even in his very interesting chapters he falls into the inorganic trap. He becomes enmeshed in a net of spectroscopic read-out. In fact I surmise that the reason this book omits two of the three fields of inorganic biochemistry, solid state structures and control, is that this chemistry belongs to the elements sodium, potassium, magnesium and calcium. The inorganic chemistry of these elements is taught no more because there are no spectra to tease the mind. Out of sight (spectroscopy) out of mind, is true for inorganic biochemistry and for many other aspects of inorganic chemistry today.

The third function of inorganic elements in biology is catalysis. Catalysis is carried out by transition metal ions or by ions such as zinc which can be replaced by these highly spectroscopic cations. The apparatus of the physical chemist can be tuned in. Each of the very good chapters on iron, cobalt, manganese, copper and zinc systems, all in a variety of forms, shows very well how to examine the active site but, while using these exciting tools, I miss the answers to the questions: Why has biology finished up with a few metals, in a few sites? Why zinc for acid catalysis and not copper? In fact I find myself asking: Who says that the role of these metal ions is as catalysts? Perhaps, through their special stereochemistry, they just generate curious organic chemistry in the active site region.

Is the role of the inorganic component too muddled with the role of the organic to be extractable? Who says ferredoxins are just electron-transfer proteins? I could be persuaded that they are really just electron traps and storage units. Their design is associated with the establishment of an electron at a redox potential close to that of the hydrogen potential but such that they do not blow off hydrogen. If my points are relevant the problem of building inorganic model systems is not what it seems to be for the overriding consideration is a control over thermodynamic not spectroscopic properties and sometimes even a prevention of a reaction. Biology has to store electrons (and elements) and it has to control activity as

well as to catalyse reactions. By looking at spectroscopic signals too closely there is the danger that the purpose of biology is lost.

Clearly this book is extremely valuable for the specialist, but when it appears on library shelves (it will not appear anywhere else at \$ 105) it must be catalogued under Inorganic and not Organic Chemistry using the real meanings of words.

R. J. P. WILLIAMS

Primate morphology

Form and Pattern in Human Evolution: Some Mathematical, Physical, and Engineering Approaches. By Charles Oxnard. Pp. ix+218. (University of Chicago: Chicago and London, 1973.) £5.65.

THE scientific basis for primate morphological and evolutionary studies has widened dramatically in the past two decades. This book describes both the more established of these new techniques as well as others whose robustness and application are still being investigated.

Charles Oxnard is the doyen of this rapidly expanding 'technological' approach to primate morphology. It is much to his credit, and to the credit of the schools at Birmingham and Chicago, that hypotheses in studies of both extant and fossil primates are now being tested by experiment and analysis. The examples he gives of the application of these techniques are almost exclusively of work by these two schools and a more cynical reviewer than I might be justified in suggesting that a comprehensive collection of Oxnard's reprints would save the cost of the book!

This somewhat parochial approach has led to two significant omissions. The first is the lack of any assessment of the biomechanical analyses of extant and fossil primate limb material that have been published recently by Preuschoft. Many workers have been waiting for someone of Oxnard's competence in this field to assess the relative proportion of wheat and chaff that is contained in this particular technique.

A second, more important, omission is that allometry is not seriously considered. A significant part of multivariate morphometrics has been concerned with the identification of the effects of size on shape. A review and discussion of the role of factor and principal component analysis in such studies and of the work of Jolicoeur, Gould and Reyment would have been welcome.

Apart from two introductory chapters, and a useful chapter devoted to simple testing procedures, the book is devoted to explanations and the applications of multivariate, group finding, stress and optical data analysis. With-

out exception these expositions make the most complicated methods plain. The chapters on multivariate morphometrics and optical data analysis are particularly good. It is a shame that in the former chapter, the author has been tempted into making over-zealous phylogenetic interpretations of the results of the shoulder girdle analysis. The new axes generated through the universe of data on the shoulder do indeed seem to have a functional, but not necessarily evolutionary, significance. It would be a pity if this classic study of function and morphology is affected by the fallacy that the proximity and sequence of extant groups is a guide to their phylogenetic relationships. This same fallacy has bedevilled so many molecular biological phylogenetic studies.

A point of minor confusion is the use of factor analysis as an umbrella term to include principal components analysis; there are of course differences between the two techniques.

These criticisms do not seriously detract from any of the books usefulness; I learned much from reading it. Students and research workers would be well advised to buy and read it. Its careful production and accuracy are a credit to the author.

There is a danger that these increasingly complex methods will separate still further the 'experimental' primate morphologists from those who study hominid fossils and evolution. A few people try to do both and it is more important than ever to see to it that further polarisation of these two groups does not take place.

BERNARD WOOD

Pin down an attitude

Attitudes and Their Measurement. By Nigel Lemon. Pp. vii+294. (Batsford: London; Halsted: New York, December 1973.) £4.20.

THERE are two schools of thought on the usefulness of the concept of 'attitude' in the social sciences in general and in social psychology in particular. School A, to which Dr Lemon belongs, treats 'attitude' very seriously and regards it as "social psychology's central problem", its study being specially important when it is resistant to change and when it clashes with 'social structural' factors. School B, to which my sympathies incline, is described by Dr Lemon as "a substantial group who would deny the need for such a term and who would argue that attitude adds nothing to existing explanations of conduct in social structural terms".

The attempt to measure attitude was initiated by L. L. Thurstone in 1929, although as an explanatory device, it had been employed, in 1918, by W. I.

Thomas and F. Znaniecki; and it was pushed into the limelight by G. W. Allport's studies of personality in 1935. The passage of four decades since then, and the hundreds of papers on the subject cited by Dr Lemon, leave the sceptical reader with the suspicion that there is not a great deal to show for all this effort. Dr Lemon does not turn a blind eye to the critics, and he is acutely aware of what he calls "the widening gulf between the increasing sophistication of measurement and the relatively crude conceptualisation on which it is based". He treats attitude as an inference from observations, a latent process, a so-called "intervening variable". It is not, in his view, merely a descriptive expression to be defined as "the probability of occurrence of defined behaviour in a definite situation".

Whatever the explanatory merits of the concept, it must be conceded that Dr Lemon has taken pains with this work. He has immersed himself in the literature, and mastered a wide range of techniques of 'measurement'. He deals with the underlying logic of the subject, with self-administered inventories, with indirect assessment procedures, with the structure of attitudes, and with models of scaling stimuli and responses.

While praising the author's commendable skill in cogent presentation, I nevertheless still wonder how he has succeeded in allaying his own misgivings as to "crude conceptualisation". And the sceptic, whose reservations are not dispelled by a display of technical virtuosity, will continue to seek more convincing explanations of social behaviour.

JOHN COHEN

Enzymes attached

Immobilized Enzymes. By O. R. Zaborsky. Pp. 175. (CRC Press: Cleveland, 1973.) \$26.50.

DURING the past decade, many hundreds of scientific papers and tens of reviews, some good, others bad, have been published on immobilised enzymes. Here for the first time is a comprehensive book giving a reasonably balanced and objective survey of the subject.

Much of the published work has been concerned with immobilisation techniques and this is reflected in this book, almost two thirds of which are devoted to chapters describing the various techniques for immobilisation: covalent attachment, intermolecular cross-linking, adsorption, entrapment, microencapsulation and containment by semipermeable membranes. In each of these chapters, many individual methods are given, and the properties of the resulting products are described. The remaining chapters are on enzyme reactors, applications and related topics.

The scientific literature, including patents, is covered in detail up till the end of 1971. With so many scientific publications on immobilised enzymes appearing in the last two years, it is inevitable that certain aspects, for instance treatments of diffusional limitation and reactor operation, are already out of date. Lists of more recent literature are, however, available from the Corning Glass Company, USA. The chapter on applications, both industrial and analytical, inevitably is rather short of data, and as the author points out is not a true reflection of the work that has been done in industrial laboratories which in some cases is far ahead of anything published.

Nevertheless, this is an excellent book and is recommended as a useful introduction and guide for anyone wishing to acquaint himself with immobilised enzymes.

M. D. LILLY

Blue-green biology

The Biology of Blue-Green Algae. Edited by N. G. Carr and B. A. Whitton. Pp. x+676. (Blackwell Scientific: London; University of California: Berkeley, 1973.) £13.50.

The Blue-Green Algae. By G. E. Fogg, W. D. P. Stewart, P. Fay and A. E. Walsby. Pp. ii+459. (Academic: London and New York, November 1973.) £8.50; \$24.

IN times past it was usual to seek specialised information about the 'biology' of a group of organisms from ancillary sections in a major work on taxonomy, structure and reproduction. The algae were no exception, but the growing number and specialisation of biological disciplines has led to greater dependence upon reviews and occasional multi-author monographs or compendia with emphasis upon physiology, biochemistry, ecology, genetics and fine structure. The first book is a good example of the latter: with 26 contributors it has a pleasantly international flavour. In this respect, and in size and coverage, it differs from the only previously comparable work, edited by Federov and Telitchenko and published (1964) in Russian under the same title.

The 25 chapters, and 4 appendices (on cultures), are often written with considerable individuality and personal outlook—the fascinating contribution on ecology in hot springs by Castenholz is a notable example. As the editors admit, the coverage of the entire subject is uneven; some important fields (such as mineral nutrition, kinetics of growth and photosynthesis) receive only passing mention, although some specialised topics are treated in detail. The single bibliography and subject plus organism indices are valuable features, but the

book is basically a collection of independent, authoritative reviews. It constitutes an excellent and readable source of information on very many topics of the relevant biology: for a really integrated account, the reader must turn elsewhere.

He could not do better than to read the second book, *The Blue-green Algae*. Although written by four authors, their contributions merge into an organised pattern of topics and coherent style wherein preferences of individuals can only be recognised by the *cognoscenti*. The brief introduction should stimulate, after which a course is steered through three main phases of structure, physiology and ecology. An early chapter on general form and structure will be the more familiar classical area, and an essential foundation, after which deeper and more recently charted waters are traversed. First appears fine structure, and then aspects of cell physiology. Overall physiology is expressed in a chapter on culture, nutrition and growth, after which follow aspects of metabolism (photosynthesis and chemosynthesis, heterotrophy and respiration and nitrogen metabolism). Structural aspects again come to the fore briefly in an account of reproduction and cellular differentiation, but the rest of the book deals extensively with external relations—in ecology (freshwater, marine and terrestrial), pathogens and symbiotic associations. The exposition is clear and authoritative, the illustrations and figures numerous and helpful, the bibliography excellent for both classic and modern work. In the book's 'connective tissue', linking intensively studied 'nodes' of structure, physiology and ecology, speculation is frequent and enticing—the discussions of vertical stratification in ecology, of plastid origin, and of early evolution provide examples.

The two books are complementary as well as overlapping: though the second is a balanced unity, the first contains more detailed accounts of some topics. The coverage achieved will be the envy of addicts to other groups of algae, and the remarkable array of biological characteristics presented will surprise many. To both works is the comment (on the first) of T. D. Brock apt—"the blue-green algae finally come into their own".

J. F. TALLING

Bigger means better

Evolution of the Brain and Intelligence. By Harry J. Jerison. Pp. xiv+482. (Academic: New York and London, December 1973.) \$25; £11.75.

THIS book covers the evolutionary development of the vertebrate brain. The author's views are expressed very clearly and the whole is well illustrated. A large number of tables and graphs gather to-

Slime mould

STAGES in the differentiation of the cellular slime mould, *Dictyostelium discoideum*, from independent myxamoebae to a multicellular organism containing two cell types. *a*, Aggregating myxamoebae; *b*, migrating 'slugs' containing several thousand cells; *c-e*, differentiation of the slug into two cell types, spore and stalk. From *The Fungi: An Advanced Treatise* (vol. 4B, *A Taxonomic Review with Keys: Basidiomycetes and Lower Fungi*), edited by G. C. Ainsworth, Frederick K. Sparrow and Alfred S. Sussman (Academic; New York and London, December 1973.) \$28.00; £13.15.

gether much of the original evidence and there is a critical handling of the data and its statistical analysis. Since the evidence presented is mainly palaeontological the size of the brain and its outer shape are the main data. From these data are woven a theory of the evolution of intelligence. As the author rightly says "The most controversial facts in the book will probably be associated with the extensive use of the evidence of relative brain size. There is no debate about the validity of the measure. There is a debate, however, about their meaningfulness".

A trivial answer to the meaning of brain size is that it is an index of the number of nerve cells. The evidence for this is presented. It is not of course possible to discuss the degree or nature of interconnection between the nerve cells by using whole brain size. Since this measure cannot be used, the author accepts the conclusion that bigger means better or at least more intelligent.

But before one can proceed to examine which brains are bigger and therefore better, one must first eliminate what might be called the brain/brawn problem because the most obvious factor varying the size of the brain of animals is the size of the animal itself. This

effect is repeatedly and convincingly illustrated. There is a straight-line relationship with a $2/3$ slope between the log of the brain weight and the log of the body weight. This applies within a species and between related species. It even applies over pretty widely scattered species. Fish and reptiles make up one line. Birds and mammals including primates make another parallel line with a bit more brain for each ton of body.

This itself has always seemed to me one of the most surprising facts about brains. Why does a little man have a little brain? Why does it take a huge brain to run a huge dog like a Great Dane whereas a much smaller brain can make a fox terrier or a cairn behave just like a dog. There is no evidence that the Great Dane has more data to analyse in proportion to its body mass except for the relatively small input from his muscles. There is no reason why the motor machinery should need to be expanded as the mass of muscle increases.

In spite of this being the basic fact, it is taken by the author as his base line and he really examines deviations from the base line without really attempting to explain the curious fundamental relationship between brain and body weight.

Fifty million years ago, early horse brains expanded in relation to their body weight but in subsequent horse development the brain increased only in proportion to the body. That early spurt is used to explain why horses are so smart and the later expansion with body size is accepted as a fact of brain life. By implication, the base line represents "the brain tissue needed to transmit impulses to and from the integrative centres" to quote the author's quotation of Lashley. The excess brain is a measure of behavioural capacity in the author's view.

The facts about the growth of brain size are well presented; the meaning of the data is more puzzling. If the excess of brain size beyond that expected for body size were a measure of behavioural capacity, we should be able to spot our academic and political leaders at a glance and they would in fact be the giants they consider themselves to be.

P. D. WALL

Peat

Peatlands. By P. D. Moore and D. J. Bellamy. Pp. vi + 221. (Elek: London, January 1974.) £4.

THE growing interest in peat and in peat-forming ecosystems, both from the ecological and from the commercial points of view, has led to a series of major international peat congresses in recent years. This book, by two of Britain's most knowledgeable and widely-travelled 'peatniks', summarises much of the work that has resulted from these congresses, and provides an invaluable source book on peatland ecology, utilisation, and conservation. In the opening chapters a detailed, and largely original, account is given of the morphologically distinct peatland types recognisable in Europe and North America, and of the climatic, hydrological, and geochemical factors governing their distribution. Of particular interest is the section dealing with the striking surface patterns of peat ridges and open water pools characteristic of some of these peatlands, and with the possible mechanisms by which this patterning arises.

Chapter 4 deals with the processes governing rates of peat accumulation, and with the retention and cycling of mineral ions. Successive chapters then consider structural and physiological adaptations in mire organisms, and the information about peatland development that can be gained from a study of plant remains preserved in the peat. The final chapters discuss the world distribution and exploitation of peatlands, and present a scientific case for more concerted and intensive conservation of peat-forming ecosystems.

Although this book contains much

that is excellent, there is also much that is sub-standard. Surely it was not necessary for the publishers to reduce some of the diagrams to such a size that details are no longer decipherable, nor to split Figs 2.4 and 6.6 each into two halves on non-opposing pages. Misspellings and inconsistencies of usage are frequent, and an almost total lack of hyphens in the text leads to many perplexities: is not the concept of "peat forming vegetation" botanically and grammatically irreconcilable?

This is, then, a book and reference source to recommend to all those interested in peat and peatlands; but one that, because of the abundance of apparently unnecessary ecological jargon in some chapters, will not perhaps be readily comprehended by persons without specialist background knowledge.

JOHN H. TALLIS

Monument to microbes

Microbiology, including Immunology and Molecular Genetics. By Bernard D. Davis, Renato Dulbecco, Herman N. Eisen, Harold S. Ginsberg, W. Barry Wood, jun. and Maclyn McCarty, (Second Edition). Pp. xv+1562. (Harper and Row: Hagerstown and London, 1973.) \$27.50.

THIS is an impressive book in scope, size and authorship. Clearly Gray's *Anatomy* can no longer claim a monopoly that, by bulk and weight, it can simultaneously generate a hernia and profound depression in the medical student who handles it! Any student depression initially engendered by the obvious mass of knowledge purveyed in this volume must surely be offset by the subsequent discovery of a pleasant, readable style, clear, helpful diagrams and illustrations, and a splendid layout.

The vital statistics of this second edition command respect—94 of the 1,562 pages are needed to index its 64 chapters! Substantial revision has occurred and new chapters have been introduced to keep pace with the relentless march of knowledge. The untimely death of Barry Wood necessitated contributions on the pathogenic bacteria from a panel of experts (who reveal their presence by eschewing SI units) under the special editorship of Maclyn McCarty. The book is divided into five principal sections comprising bacterial physiology, bacterial and molecular genetics, immunology, bacterial and mycotic infections, and virology, and, as might be expected from such distinguished authors, the overall treatment is very good, with emphasis on scientific method. The avowed intention to produce a text that tells the medical student not only what is known but how it came to be known, has been

amply realised.

Inevitably in a book of this size there are points to criticise. Thus the claim that bacterial glycogen synthesis involves uridine diphosphate glucose, confusion between free and standard free energy changes, and omission of the unifying concept of adenylate energy charge when discussing metabolic regulation, are some of the blemishes I noticed. But they do not detract significantly from a monumental work which should provide not only students of medicine and the paramedical sciences but also their biological colleagues with a very useful and comprehensive text.

E. A. DAWES

Deep sea fish

Fishes of the Western North Atlantic, Part 6. (Memoir of the Sear Foundation for Marine Research, No. 1.) Pp. xix+698. (Sears Foundation for Marine Research, Yale University: New Haven, 1973.) \$27.50.

THE series of publications under the general title of *Fishes of the Western North Atlantic* is too well known to need introduction. The first volume, produced in 1948, was written entirely by the late H. B. Bigelow and W. C. Schroeder and quickly became a classic source of information on the sharks with which it dealt. It set a standard of excellence which seemed to be almost too high to be maintained in succeeding volumes. Twenty-five years later the sixth part of the series has been published and shows convincingly that the standard is in no way diminished.

Two important policy changes are announced with this volume. First, that in future material will be published as it becomes available rather than in systematic order (and thus waiting for laggard contributors). The second change is to permit publication of new taxa within the volume rather than insisting on prior publication elsewhere. Both changes make good sense as attempts to speed the production of further volumes towards the eventual coverage of the western North Atlantic fish fauna.

Part 6 of the FWNA contains the following contributions: the order Heteromi (Notacanthiformes) by S. McDowell, the suborder Cyprinodontoides (the brackish and salt-water killifishes) by Donn E. Rosen, the order Berycomorphi (Beryciformes) by Loren P. Woods and Pearl M. Sonoda, the order Xenoberyces (Stephanoberyciformes) by A. W. Ebeling and W. H. Weed, and the Macrouridae (rat-tails or grenadiers) by N. B. Marshall and Tomio Iwamoto, preceded by a general account of the order Anacanthini (the Gadiformes or the cod fishes). To

produce a collection of contributions by so many authors is a major feat on the part of the editor Daniel M. Cohen and his editorial board.

Most of the groups treated in this volume are deep-water fishes which have presented many taxonomic problems in the past. Many of them are also known from relatively few specimens. The value of the volume is therefore very considerable.

McDowell's contribution in unravelling the complicated synonymy of species of spiny eels and halosaurs is a major feat of taxonomy, to which is added a penetrating account of the anatomy and relationships of these fishes. McDowell has summarised the literature and much unpublished information on the distribution and biology, as well as giving detailed accounts of structure and morphology of each species.

Rosen's discussion of the killifishes or euryhaline toothcarps is necessarily different from the other contributions, for this group is primarily freshwater with relatively few euryhaline species. All the marine or brackish toothcarps found on the American Atlantic coast are listed, with notes on their range, clear illustrations, and with a key for their identification.

The berycoid fishes comprise a mixture of deepwater "soldiers", *Hoplostethus* and other genera, together with

Jellyfish

Aequorea victoria, the largest common jellyfish in the area covered by *Seashore Life of Puget Sound, the Strait of Georgia, and the San Juan Archipelago*, by Eugene N. Kozloff. (University of Washington: Seattle, November 1973.) Boards \$15.00; paper \$6.95.

the squirrel fishes (Holocentridae), mainly shallow water tropical fishes. Again, many taxonomic problems were evident in this group which Woods and Sonoda have clarified. It is comforting to see such a troublesome spectre as *Hoplostethus islandicus* of German fishery workers finally laid as a junior synonym of *H. atlanticus*!

The contributions of Marshall and Iwamoto have brought together the widespread literature on the rat-tails (Macrouridae) in a way which will facilitate the identification of these difficult fishes. An elucidation of this group is particularly timely as the rat-tails, the dominant fish group of the lower continental shelf, are becoming increasingly attractive as commercial fishes. Russian exploitation of the northern *Coryphaenoides rupestris* has already reached considerable proportions and wider interest in this relatively well-flavoured fish can be predicted.

ALWYN WHEELER

Taxonomy without genes

Numerical Taxonomy. The Principles and Practice of Numerical Classification. By Peter H. A. Sneath and Robert R. Sokal. Pp. xv+573. (A series of Books in Biology.) (Freeman: San Francisco, October 1973.) £9.40.

THIS is not a second edition of Sokal and Sneath's well known 1963 book on numerical taxonomy but a completely new work. The authors' aim is to provide a comprehensive and up to date account of the subject and to illustrate the advantages of numerical over conventional taxonomy.

It is certainly a very careful and detailed review, and will be of great value to anyone with a professional interest in this field. It is not a book for someone wishing to 'find out about numerical taxonomy'. Readers are referred to the original papers for many of the details and the mathematical notation, although logical and consistent, produces such mind-bending conjunctions as

$$t_{j,1} = \sum_{i=1}^J X_{ij}.$$

When these ingredients are added to the already gross terminology of conventional taxonomy the result is hard going even for people experienced in the field.

The first three chapters on taxonomic principles and evidence provide the background for the rest of the book. The choice and coding of characters is discussed and the authors make it clear that this is the least satisfactory aspect of numerical taxonomy. Chapters 4 and 5 on taxonomic resemblance and structure form the core of the book and chapter 6 deals with methods of esti-

mating cladistic relationships. This last should be particularly useful as it collects together, for the first time, a lot of recently published material. There is a chapter on identification, including the automatic generation of keys; a chapter on populations; a chapter on nomenclature; and a few bits and pieces. The bibliography is vast and there is also a list of applications of numerical taxonomy to systematics, classified by the group of organisms. An author and subject index ends the book.

The authors' basic position (highly paraphrased) is that a purely phenetic classification system would have great advantages for biology in general. Genetic and phylogenetic information should be irrelevant to the classification (however interesting in its own right). Old ideas about phenetic resemblance estimating genetic resemblance have been thrown overboard and the good ship SS Phenetics is now sailing under its true colours. The authors accept that the lack of a satisfactory definition of 'character' is a theoretical weakness, but claim a certain robustness in practice. They also state that, in time, numerical taxonomy will become objective, and criteria for grouping will be agreed by common consent.

The very size and complexity of the book makes this last claim seem unlikely. A tremendous variety of techniques is mentioned and each new alternative to some act which was previously without alternative doubles the number. It may be that a book such as this is an essential first step—an inventory before taking the vote; but it seems to me more likely that what will emerge from numerical taxonomy is a set of very useful mathematical methods but no general agreement about the way in which the results of applying them should be used.

Whether one is sympathetic to the aims of numerical taxonomy or not it must be granted that to have written a book as up to date and comprehensive as this is a remarkable achievement. It will be an indispensable reference work for many years to come, proving useful to all taxonomists, not just those who obey the fiat of pheneticism.

M. HILLS

Mineral metabolism

Calcium and Phosphorus Metabolism. By J. T. Irving. Pp. viii+246. (Academic (Harcourt Brace Jovanovich): New York and London, September 1973.) £15.

INTEREST in this book is quickly aroused by its table of contents since almost every aspect of the subject is covered in an orderly and well-tabulated progression. The style is readable and there is no difficulty in locating particular topics of interest. The book is reasonably

elementary, its depth being necessarily limited by its size, but so much recent knowledge has accumulated, for example with respect to the chemistry of parathyroid hormone, to cyclic AMP and to vitamin D metabolism, that a simple overview such as this is timely. The author might perhaps have made still more use of the opportunities for critical judgment that a monograph provides but attempts to reconcile conflicting evidence are nevertheless made in a rational way. While the overall approach of the book is physiological, biochemical and clinical aspects are interwoven.

The revision for this edition is a little uneven and a few sections are still composed from largely primitive sources. Occasional statements are misleading such as the bald comment that "in myxoedema the level (of blood calcium) is unchanged". The disadvantage of long publication time is apparent particularly in the expanding field of vitamin D metabolism where the most recent references are over 2 years old. Nevertheless this remains an excellent, concise book for students of the field and will also be of value to specialists when they require to look into other physiological aspects of their subject.

T. C. B. STAMP

Ukrainian hunters

Ice-Age Hunters of the Ukraine: Prehistoric Archaeology and Ecology. By Richard Klein. Pp. xviii+140. (University of Chicago: Chicago and London, 1973.) £2.95 boards; £1.35 paper.

THIS small book serves two purposes. First it is a very welcome up to date summary of Soviet research in the upper Palaeolithic of the Ukraine, and, second, it makes available material not readily accessible to Western readers who do not read Russian fluently.

The author takes the occupation of the Ukraine during the Last Glaciation, roughly from about 45,000 to 10,000 years, which covers the Mousterian as well as the Upper Palaeolithic.

The preface and the early sections suggest that the author has undergraduates in mind and this has had some effect on the whole tone of the book, but this approach in no way detracts from its usefulness. Both the archaeology and the supporting studies, geology, fauna and pollen studies, are dealt with in some detail with the result that the area and period are dealt with as a whole, including discussion of the environments during the three stages of the Last Glaciation. This evidence is illustrated by maps, pollen diagrams and faunal lists.

The archaeological side, which is the main purpose of the book, deals very fully with the evidence for dwelling

structures, the earliest of which date from the Mousterian. These houses are mostly constructed from mammoth bone, an animal which forms the bulk of the economy, and whose bones (skulls, long-bones, scapulae and tusks) in a region with a timber shortage, made good building material. In addition to hut plans and their reconstruction, the author reproduces some of the archaeological material, but unfortunately, though being quite generous with his illustrations of the bone objects, gives no useful illustrations of the flint assemblages.

When one looks at the list of references at the back one can only be very grateful for the mass of material that the author has condensed. This is a very useful book and most prehistorians, not excluding Russians, will be glad of it.

J. D'A. WAECHTER

Statistics for biologists

Biostatistical Analysis. By Jerrold H. Zar. Pp. xiv+620. (Prentice-Hall Biological Sciences Series.) (Prentice-Hall: Englewood Cliffs, NJ, 1974.) \$25.95.

WHETHER or not statisticians regard the practice as desirable, many biologists choose to be responsible for their own statistical analyses. To aid them, they have a great many bad and a few good cookery books. Professor Zar's thorough presentation of detailed formulae and abundance of worked examples places him firmly in the second category. Those who are prepared to handle a rather heavily formalised symbolism should welcome this well-produced text. The descriptions of analysis of variance calculations and their associated tests of significance are particularly clear. Perhaps the chief weaknesses are the lack of critical guidance on choice between methods (when should a non-parametric technique be adopted for analysis of a continuous variate?) and the unfortunate habit of presenting the scaffolding of tests of significance without summary tables of means.

More than 200 pages of tables of statistical functions are included. Today's computer facilities, and the availability of keys for standard functions on relatively cheap desk calculators, could have allowed substantial omissions and condensations here, with consequent reduction in the high cost of the book. The attitude to computing, indeed, is surprisingly old-fashioned. Little is said about any sophisticated programming. Such uses of computers as are described are concerned merely with performing the heavy arithmetic and with the barbarity of floating point output.

The book evidently originated in a concern for statistical analysis of observational data rather than planned experiments. This emphasis is valuable,

though it could usefully have been supported by more discussion of sampling of biological populations and materials, selection of observations and measurement procedures. Particularly interesting is the chapter on distributions of angular directions, a topic rarely mentioned in elementary texts.

D. J. FINNEY

Wobble in the glance

Eye-Movements and Visual Perception. by R. W. Ditchburn. Pp. xv+421. (Clarendon: Oxford; Oxford University: London, December 1973.) £9.50.

WHEN we wish to scrutinise an object and look at it in great detail we point our eyes towards the thing and hold them quite stationary—or so one might think. But even during periods of concentrated fixation, the eyes are never really still. They move constantly with three components of motion: a slight tremor (about 50 Hz, amplitude about 20 arc s) probably originating in the intrinsic noise of the extraocular muscles; slow drift (velocity up to 20 arc min s⁻¹); and intermittent, tiny, fast flicks (usually one or two per second, mean amplitude 5 arc min).

Our normal persistent perception of the visual world must depend on one or more of these apparently involuntary movements because if an optical device is used to hold an image more or less fixed on the retina, despite eye movements, the pattern seems to fade virtually completely within a few seconds. Isaac Newton was perhaps the first to recognise this necessity for a moving retinal stimulus. He noticed that pressing the side of the eyeball with a finger stimulates the retina mechanically, producing a coloured blob superimposed on the visual field; however "if the eye and the finger remain quiet these colours vanish in a second minute of time, but if the finger be moved with a quavering motion they appear again"¹.

Since Newton's time there has been more than a little research on the small eye movements of fixation and the curious phenomena that occur when the retinal image is stabilised. Ditchburn's book is a critical catalogue of this work, invaluable to the researcher in this area and of interest to every student of vision. This book, then, has a place as a companion (but not a complete successor) to the highly personal account of eye movements and visual perception by A. L. Yarbus².

Ditchburn begins with a general introduction to visual optics and the problems introduced by movements of the eye. He then provides a most useful review of all the methods of recording eye movements and evaluates them critically.

This section, together with an appendix containing many technical details, is of great value to anyone intending to work in this field where instrumentation is so varied in scope and quality and where the recording apparatus itself imposes severe restrictions on the kinds of movements that can be accurately monitored.

Next comes a survey of the results of these recording experiments with a wealth of quantitative data from many different workers. Ditchburn then discusses the various kinds of apparatus used for producing a more or less stationary retinal image despite movements of the eye. Most involve the wearing of a closely fitting contact lens with various appendages such as a sucker, to hold the lens tightly to the cornea, a mirror on a long stalk or even a miniature projection system complete with lens and light bulb. Some of these devices would have made the Spanish Inquisition green with envy. Unfortunately not all these methods are equally efficient in holding the retinal image stationary: consequently the various introspective reports on changes in colour, brightness and clarity of stabilised images are not all equally valid and it is sometimes difficult to know how to evaluate them.

Before considering the causes of perceptual fading of a stabilised image and the function and control of small eye movements, Ditchburn reviews briefly the relevant physiology of the visual system. But let me be clear: this is not the place to learn about the latest advances in visual physiology. This is perhaps the weakest section of the book, but is adequate for the question in hand.

Ditchburn concludes that no single type of small eye movement (tremor, drift or saccade) is adequate to maintain the normal visibility of the image. He believes that both drifts and saccades are essential. It is worth mentioning that not everyone agrees. Steinman and his colleagues³, for instance, have found that some observers can learn to suppress small saccades completely, without decreasing the accuracy of fixation or the visibility of the target.

Finally, a word about the index. The book is organised into numbered subsections of each chapter and these are used (rather than page numbers) in the index. No doubt this is a great economy in editing and layout but it is a very clumsy system to use. I hope that any future edition of this book may have a real index as well as answering many of the unsolved questions in this fascinating field.

Fragmentation of the Alpine orogenic belt by microplate dispersal

Walter Alvarez

Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York 10964

Tommaso Coccozza

Istituto di Geologia dell'Università, Via delle Cerchia, 5, 53100 Siena, Italy

Forese C. Wezel

Istituto di Geologia e Paleontologia dell'Università, Via Zamboni, 67, 40127 Bologna, and
Istituto di Scienze della Terra dell'Università, 61029 Urbino, Italy

Reconstruction of the positions of western Mediterranean microplates in the Oligocene leads to recognition of a formerly continuous 'Alpine' (Mesozoic-Eocene) orogenic belt. This Alpine belt was fragmented by Miocene to Quaternary microplate dispersal in which four episodes of movement are recognised.

It is becoming increasingly clear that the movement of microplates such as Corsica-Sardinia^{1,2} and Spain³ has played a principal role in the tectonic evolution of the Mediterranean but it is difficult to find clear evidence for the exact time and manner in which these and other microplates have moved^{4,5}. Here we attempt to reconstruct the history of late Tertiary microplate movement in part of the western Mediterranean; the evidence will be reviewed in more detail in a forthcoming paper. The first step in this study is to determine the palaeogeography in the Oligocene, before the latest episode of microplate dispersal; the second step is to determine the pattern of movement of the microplates. If the reconstruction given here is correct, it explains the longstanding question of why the Eocene orogenic belt of the Alps terminates in northeast Corsica and clarifies the origin of the Miocene orogenic belt of Italy, Sicily, and North Africa (the Apennine-Maghrebian fold belt).

Oligocene palaeogeography

Figure 1 shows a reconstruction of western Mediterranean palaeogeography in the Oligocene, that is, after the 'Alpine' orogeny in the Cretaceous to Eocene but before the 'Apennine-Maghrebian' deformations of the Miocene. The first step in making this reconstruction is to place Corsica and Sardinia next to Provence. Evidence for this fit has been reviewed¹; further evidence from palaeomagnetism^{6,7} and geological matching⁸ has been reported. Corsica and Sardinia are separated by the Straits of Bonifacio, an opening which widens westwards and which may be a 'microspinochasm'^{4,8}. A greater rotation for Sardinia than for Corsica has been assumed here⁸ in order to close the Straits of Bonifacio, improve the geometrical fit with France and better satisfy the palaeomagnetic data⁷. The 'eugeosynclinal' sequences occurring as allochthonous nappes and slabs in the northern Apennines were originally deposited in the area between Corsica and Italy^{9,10}, and the internal (that is, originally south-western) parts of the eugeosyncline must have been within the Alpine belt since they were deformed

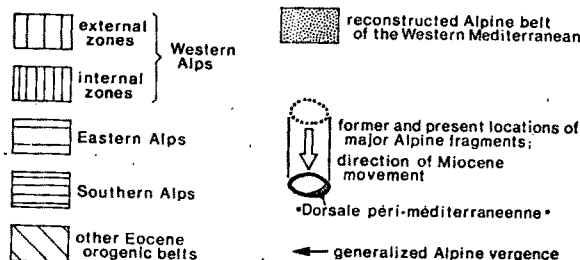

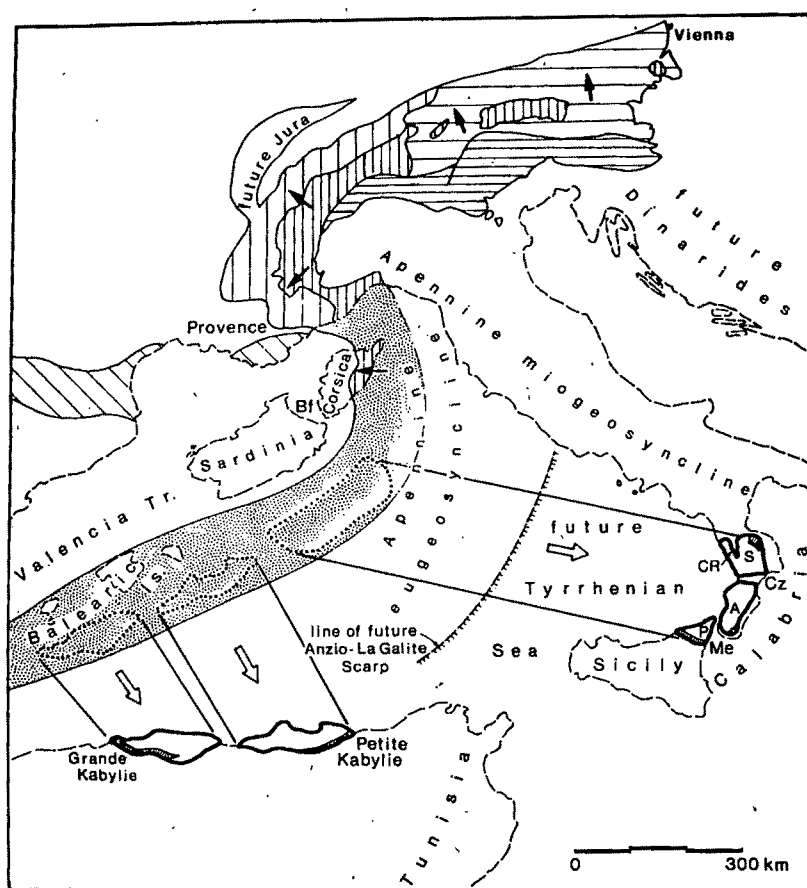

in the Palaeogene¹⁰⁻¹². The external parts of the eugeosyncline lack a Palaeogene unconformity and were thus outside the Alpine belt.

As the next step we propose that the crystalline Calabrian 'massif' of southernmost Italy and NE Sicily should be placed next to Sardinia. This massif, 200 km long and 50 km wide, links the NW-SE trending Apennines with the east-west Maghrebian trends. It is a unique element in the otherwise sedimentary sequences of the Apennines, but most of its characteristics are repeated in the two Kabylie massifs of Algeria and the Rif massif of Morocco. The Calabrian massif is split into three segments by the Straits of Messina and the Catanzaro lowland; we suggest that these transverse depressions may be 'microspinochasms' due to fragmentation of the massif during its south-eastward movement.

Evidence for the former position of Calabria shown in Fig. 1 is provided by (1) similarities with Alpine Corsica; (2) sediment supply requirements; (3) similarities with the Kabylie massifs; (4) the present movement of the massif and (5) displacement of the Numidian flysch-crystalline massif suture 300 km south-eastwards from Tunisia to NE Sicily (discussed in the final section).

(1) Calabria is not, as has often been implied, a Hercynian massif unaffected by tectonism since the end of the Palaeozoic. Rather it is a stack of nappes (some containing Hercynian crystalline rocks) that, according to some authors¹³⁻¹⁵, were emplaced during the Eocene, that is, at the same time as the nappe emplacement in NE Corsica¹⁶. The direction of movement of the Calabrian nappes is currently a matter of debate, so this aspect cannot be compared with Corsica, but there are close analogies in lithology and metamorphism (high *P/T*) between Calabria and NE Corsica. Both areas contain phyllites and schists with ophiolites and metabasic rocks—the 'schistes lustrés' of Corsica¹⁷⁻²⁰ and various units with controversial nomenclature, some of which have been referred to as 'schistes pseudolustrés'²¹, in Calabria^{13,22-24}. Blueschist metamorphism is found in both areas^{13,24-26}; elsewhere in the western Mediterranean it is known only in the French Alps²⁷ and in the Betic Cordilleras²⁸. All four areas are part of the reconstructed Alpine belt of Fig. 1.

(2) Two sedimentary units on or adjacent to the Calabrian massif (Fig. 2) seem to require sources of detrital material in Sardinia: the Tusa andesitic flysch, recently shown to be late Oligocene-Aquitainian in age²⁷ seems to be a trench deposit^{30,31} and the late Oligocene-early Miocene volcanic province of western Sardinia seems to be the only available source of calc-alkaline detritus^{29,30}; the transgressive Capo d'Orlando flysch, which covers the NE Sicilian part of the Calabrian massif and is probably an arc-trench gap deposit²⁹,

contains clasts of a red porphyry found in place in Sardinia but not in southern Italy or Sicily³².

(3) We also note the similarity between the Calabrian and the Kabylie massifs in orogenic timing^{33,34} and in the precisely analogous Mesozoic cover of the 'Dorsale péri-méditerranéenne'³⁵ ('Chaîne calcaire') in the two areas^{33,36}. The 600 km gap between these massifs and the northward projection of the Tunisian shelf make either submerged continuity or separation as a result of east-west motion highly unlikely, but the similarities are explained well by the diverging motions shown in Fig. 1.

(4) The active volcanic and seismic zone beneath Calabria reveals ESE-directed motion of the massif³⁷⁻⁴⁰, indicating that Calabria is at present moving in the direction required by the reconstruction of Fig. 1.

A recent report of basement nappe movement of Alpine age in eastern Sardinia⁴¹ suggested that Alpine Calabria might have been located very close to Sardinia. Our field results⁴² however, show that the 'basement nappe' is simply a massive landslide of incompetent phyllite off the side of an early Tertiary horst. Thus Sardinia must have been well outside the zone of Alpine compression. We tentatively assume that the elongated seamounts of the Monti di Quirra and the Monti delle Baronie, which trend north-south about 50 km east of Sardinia⁴³ and from which crystalline rocks have been dredged⁴⁴, are part of the Sardinian continental crust. This suggests that the Calabrian block should be placed east of these seamounts, 50-100 km east of the present coast.

FIG. 1 Reconstruction of the locations of western Mediterranean microplates during the Oligocene after the final Alpine phase in the Eocene but before the Apennine-Maurebian movements in the Miocene. The probable closure of the Valencia trough has not been shown since data for accurate reconstruction are lacking. This interpretation uses a greater angle of rotation for Sardinia than for Corsica, thus closing the probable sphenochasm of the Straits of Messina (Bf). The present positions of the Alpine fragments are shown by heavy lines. The Calabrian 'massif' is broken in three parts by the Catanzaro (Cz) and Messina (Me) sphenochasms. CR, Coastal Range; S, Sila; A, Aspromonte; Serra San Bruno; P, Peloritani Mountains.

Although less evidence is available than for the preceding fit, we make an analogous reconstruction to the southwest, first closing the Valencia trough⁴⁵ and then placing the Kabylie massifs against the Balearic Islands on the basis of the Calabria-Kabylie similarities already noted and of the Sardinia-Kabylie similarities discussed by Vardabasso⁴⁶.

During the Oligocene and early Miocene there must have been an oceanic basin south-east of Calabria with the Tuscan andesitic flysch⁴⁷, discussed previously, deposited in a trench on the north-west side, and the continental rise deposits of the Numidian flysch on the south-east side³⁰. According to one of us, the Numidian quartz sands were derived from the Saharan shield⁴⁸⁻⁵⁰. (Arguments, based on thermoluminescence, for a Sardinian source for the Numidian quartz have recently been shown to be invalid⁵¹.) The distribution of the Numidian shows that the Oligocene African continental margin extended from southern Spain and Morocco through north Africa and Sicily to the Anzio-Ancona line in central Italy^{20,49}. Not all this margin however, was necessarily backed by African sialic crust; it has been proposed^{4,52} that in the Jurassic an ocean basin opened between Sicily and Italy, so oceanic crust would have been continuous from the site of the present Tyrrhenian Sea into the eastern Mediterranean.

Characteristics of reconstructed Alpine belt

In plate tectonic terms the Alpine orogenic belt is generally considered to be a suture marking the closure of a small

ocean that opened in the Jurassic and early Cretaceous and closed with major episodes of crustal consumption in the middle of the Cretaceous and the Eocene⁵². The Alpine belt as reconstructed in Fig. 1 comprises the Alps proper and NE Corsica, then trends SW through Calabria and the Kabylies, and may continue into the Betic Cordilleras of southern Spain, although the orogenic history of the latter area is not yet well understood^{53,54}. From the western Alps as far as the northern part of the Calabrian massif (Coastal Range, west of the Sila) the Alpine belt is characterised by 'schistes lustrés', ophiolites, and blueschist metamorphism. From the northern Sila (Longobucco⁵⁵) through NE Sicily and the Kabylies to the Rif and the western Betic as far as Granada⁵⁵, a new element, the 'Dorsale péri-méditerranéenne' or 'Chaîne calcaire', is continuously present^{56,58}. If this change had occurred between two Alpine fragments, it might have cast doubt on their continuity. But, since western Alps-type characteristics and the 'Dorsale péri-méditerranéenne' overlap within a single Alpine fragment and since Eocene orogeny is characteristic of all the fragments, the change does not argue against the proposed reconstruction of the Alpine belt.

The reconstructed Alpine belt of Fig. 1 trends WSW from Vienna to the Kabylies and possibly to Gibraltar, with an offset in the French Alps. Study of magnetic anomalies in the Atlantic⁵⁷ has permitted Pitman⁵² to determine the successive poles of Africa-Europe rotation. From the early Eocene (Ypresian; anomaly 21, 53 m.y.) to the Tortonian (anomaly 5, 9 m.y.) the average pole was at about 34.4°N, 2.5°W in the European reference frame, or about 300 km southeast of Gibraltar, and Europe and Africa approached each other with a rotation of 6.8°. This rotation probably took place mostly in the Eocene, a time of intense tectonic activity. An Africa-Europe rotation of 6.8° about this pole would cause crustal shortening of 100–200 km in the Alps, which may be compared with geological estimates ranging from 100 to 600 km⁵⁸. Thus the Alpine belt was apparently formed by crustal shortening and/or consumption during the approach of Europe and Africa; this is, of course, the classical explanation of the Alps proper.

The offset in the Western Alps may be due to a projection of the front of the overriding African plate, that is, the pro-

Fig. 2 Front of the rotating Sardinia-Calabria microplate during the early Burdigalian (second episode of movement). This reconstruction is based on geological relationships in NE Sicily and shows the Peloritan basement (Sicilian part of the Calabrian 'massif') overriding oceanic sediments north of the African continental margin prior to collision with Africa in the early Langhian. *a*, Detail of the trench shown in *b*. 1, crystalline basement; 2, limestones of the 'Dorsale péri-méditerranéenne'; 3–6, flysch and mélanges on the south side of the Calabrian massif; 7, Reitano-Capo d'Orlando flysch (arc-trench gap turbidites); 8, Subsided Panormide carbonate platform; 9, Pre-flysch of the African continental margin; 10, Numidian continental-rise sediments; 11, Radiolarites and diatomites related to volcanic episodes. This cross section is discussed in detail by Wezel²⁹.

jecting Italian block may have pushed the main part of the Alps further to the north. Alternatively, the offset may reflect a trench-trench transform fault following a small circle having its centre at the pole of rotation near Gibraltar. A

third possibility is that the Corsica-Sardinia block was part of the Iberian plate while the latter was rotating during the Eocene³ and that as this plate moved eastward it distorted the Alpine belt and produced the curvature.

Fragmentation and dispersal of microplates

In France, Switzerland and Austria the Alpine suture was caught between the two large sialic blocks of Europe and Italy. In the western Mediterranean it seems that an oceanic area remained not far southeast of the suture^{4,52} and that the microplates moved into this area. The reason for the microplate movement is not clear, although it may be related to buoyancy of crustal material subducted earlier, during the suturing. It has been suggested^{59–61} that the movements are due to back-arc extension or 'multisubduction' similar to that of the western Pacific⁶². We note, however, a possible difference: while in the western Pacific general subduction of the Pacific plate under Asia produces local upwellings that drive the island arcs back over the Pacific plate, in the Mediterranean there does not seem to have been a general subduction (for example, at present, Calabria alone is moving ESE over the Ionian Sea^{37,40}). It seems that the upwelling is the primary driving mechanism, producing only local subduction. Thus in a given episode we expect to find first volcanism, then crustal separation and microplate movement with local subduction.

On the basis of available data four episodes of microplate movement can be tentatively identified in the Tyrrhenian Sea area. The first two episodes probably had analogues to the southwest in the Balearic-Kabylie region; the third and fourth episodes are much more difficult to interpret than the first two.

The first episode involved initial rotation of the Corsica-Sardinia-Calabria microplate away from France and formation of the first part of the Ligurian Sea behind the rotating microplate. The beginning of this episode is marked by the initiation of andesitic volcanism in Sardinia in the late Oligocene—a volcanism which continued until the beginning of the middle Miocene⁶. Graben formation accompanied the volcanism in the Oligocene^{63,64} but crustal separation in the Ligurian Sea area need not have occurred immediately. We propose that the separation came in the Aquitanian, since this is the time of a rapid, regional, marine transgression over continental deposits in the Campidano lowland of SW Sardinia, an early Tertiary graben which was ideally situated to record a marine incursion at the beginning of rotation^{65,66}. (Analogous opening of the Valencia Trough probably occurred at the same time; this is supported by an age date of 22–19 m.y. on andesitic rocks cored at DSDP site 123 (ref. 45).) The end of the first episode came during the late Aquitanian when Corsica collided with the sialic crust of the northern Apennines, a collision marked by orogenic activity in the eugeosynclinal sequences of the northern Apennines^{12,67}.

Corsica was then unable to rotate further and the second episode began as the Sardinia-Calabria microplate broke away from Corsica and continued to rotate, forming the rest of the Ligurian Sea and the microsphenochasm of the Straits of Bonifacio. This separation took place in the early Burdigalian, as is shown by marine transgressions of that age in the Bonifacio basin of southern Corsica⁶⁸ and in its continuation, the Capo Testa basin of northern Sardinia⁶⁹. Volcanism related to this opening cannot be separated from the rest of the Sardinian Oligo-Miocene volcanism. The palaeomagnetism of volcanic rocks intercalated with fossiliferous marine sediments at Castelsardo in northern Sardinia indicates that Sardinia rotated rather suddenly in the early Miocene⁶; further studies⁷ suggest rotation in the late Aquitanian. These dates agree well with the timing proposed here. Figure 2 shows conditions at the leading edge of the Sardinia-Calabria microplate during the second episode of rotation, with the Peloritan continental basement (part of the Calabrian

'massif') approaching the African continental margin. This second episode terminated with the collision between the rotating microplate and the Tunisian margin of North Africa. In this collision the NE Sicilian part of the Calabrian massif (Peloritani Mountains) overrode the Numidian flysch deposits of the African continental slope—orogenic activity that

FIG. 3 Schematic diagrams to show the four episodes of tectonic evolution proposed in this paper. *a*, Reconstruction end Oligocene. *b*, After first episode, late Aquitanian. *c*, After second episode, early Langhian. *d*, After third episode, Tortonian. *e*, After fourth episode, present day. Co, Corsica; Sa, Sardinia; Ca, Calabria.

can be dated²⁹ as early Langhian (upper part of zone N-8 of Blow⁷⁰, about 14 m.y.). Collision of the independent but analogous Kabylie microplate(s) with North Africa took place very slightly earlier (lower part of zone N-8 of Blow, about 14.5 m.y., M. Durand-Delga, personal communication, 1973). The line of collision of the Sardinia-Calabria microplate with North Africa is preserved today as the submerged boundary between the Sardinian crystalline block and the Numidian flysch in the Straits of Tunisia^{71,72}. Collision of the rotating microplate with the continental mass of North Africa seems to have stopped the rotation of Sardinia, while the Calabrian portion of the microplate, facing the oceanic crust of the eastern Mediterranean-Ionian Sea, broke free and continued to move to the south-east, carrying the line of collision of the Peloritani Mountains with the Numidian about 300 km south-east to its present position.

If the reconstruction of Fig. 1 is correct, the Tyrrhenian Sea was formed in the wake of the Calabrian massif as it moved south-eastwards, but general agreement has not been reached on the time and mode of origin of this sea, and the question of spreading as against oceanisation in place is a matter of continuing debate^{45,73,75}. There are conflicting views on the age of the basin. At DSDP site 132 upper Miocene (Messinian) shallow-water evaporites are abruptly overlain in transgression by deep-water Pliocene pelagic ooze ('Trubi'); this led to the interpretation, generalised for the entire Tyrrhenian Sea, that the basin was formed before the Messinian, was dried out by evaporation during the Messinian and was suddenly flooded at the beginning of the Pliocene⁴⁵. On the other hand, a widespread Middle Pliocene transgression analogous to the Middle Pliocene transgression seen on land⁷⁵, has been suggested on the basis of dredge hauls and seismic reflection profiles⁴⁴, implying that the present basin is Middle Pliocene or younger. We suggest a possible reconciliation of these views by noting that the Tyrrhenian Sea is divided into two parts by a NE-SW trending boundary, here called the 'Anzio-La Galite Scarp'. To the north-west of this scarp is an abyssal plain without volcanoes at about -2,800 m that is underlain by horizon 'M' (top of the Messinian evaporites); DSDP site 132 is in

this area. North-south ridges^{43,74} emerge northwards from this abyssal plain, apparently forming a continuation of the tectonic ridges of the northern Apennines. To the south-east of the scarp is an abyssal plain at about -3,400 m, marked by large Plio-Pleistocene volcanoes with a NNE-SSW elongation^{43,74}. We have not been able to trace the distinctive seismic horizon 'M' across the Anzio-La Galite Scarp into the SE Tyrrhenian, nor to recognise it anywhere in this area. Thus we tentatively conclude that the Messinian evaporites are not present in the SE Tyrrhenian, at least not in the very thick, evaporated, shallow-water deep-basin facies of DSDP site 132. The SE Tyrrhenian basin may thus be post-Messinian. The possible difference in age between the two parts of the Tyrrhenian basin leads us to suggest two further episodes of microplate movement, although these are more speculative than the first two.

After collision with Tunisia the Sardinian part of the microplate was no longer free to move and the third episode began with separation of Calabria from Sardinia. This separation must have been post-Aquitian (if the Sardinian volcanics were in fact the source of the latest Oligocene-Aquitian Tusa andesitic flysch on the south-east side of the Calabrian massif⁴⁷), later than early Langhian (assuming that Sardinia and Calabria were attached until Sardinia was blocked by Tunisia) and pre-Messinian (because Messinian evaporites were deposited in the western Tyrrhenian at DSDP site 132 ref. 45). The Miocene delta of Orsei, on the east coast of Sardinia, has been dated as Helvetian (Middle Miocene), and interpreted as marking the initiation of the north-south horst of eastern Sardinia⁷⁶. Thus we suggest that the separation of Calabria from Sardinia took place in the middle Miocene, and that Tortonian deformation in Sicily⁵⁰ indicates a collision that terminated this phase of separation. The part of the Tyrrhenian Sea west of the Anzio-La Galite scarp would have formed during this third, pre-Messinian, episode of movement and would then have been the site of Messinian evaporite deposition.

The fourth episode occurred from the Pliocene to the Recent, with Calabria moving ESE to its present position. The movement of the Calabrian microplate may be reflected by greater fragmentation of the allochthonous Apennine carbonate block mountains from NW to SE: in the central Apennines the allochthonous masses average 30 × 100 km; in the southern Apennines they are smaller, averaging 10 × 40 km. The big central volcanoes of the SE Tyrrhenian, M. Vavilov and M. Marsili, are probably related to the motion of Calabria. They are located on the WNW-ESE axis of the basin along the track probably followed by Calabria (the up-dip direction of the present seismic zone) and are elongated at right angles to the basin axis^{43,44}. Dredge samples show that the volcanic rocks of M. Marsili are tholeiitic and have affinities with those of mid-ocean ridges⁷⁷. Also noteworthy is the remarkably circular pattern of the south-easternmost Tyrrhenian, with the inner ring of the Aeolian Islands-M. Palinuro and the outer ring of the southern Apennines-Calabria-northern Sicily mountains concentric about the Marsili volcano. These observations suggest that M. Marsili and M. Vavilov may mark centres of accretion in a complex, non-linear, pattern of behind-the-arc seafloor spreading.

Continuing activity is shown by the high heat flow of the Tyrrhenian Sea⁷⁸ and by the active seismic zone dipping WNW beneath Calabria and the associated volcanoes of the Aeolian Islands⁸⁷⁻⁹⁰. This narrow seismic zone must be interpreted as showing ESE-directed overriding of a small Calabrian plate, rather than general subduction of Africa, beneath Europe³⁷.

Relation to magnetic studies

Bayer *et al.*⁷⁹ give a magnetic anomaly map of the western Mediterranean and a tectonic interpretation based on this

map. Their interpretation agrees with ours in placing the Kabylie massifs among the Mediterranean microplates but differs by placing the poles of rotation of Corsica and Sardinia relative to Europe about 60° away so that there is little change in orientation of the islands during their movement. We have used poles nearby so that the islands have large total angular rotations: 32° (Corsica) and 65° (Sardinia)⁴. The palaeomagnetic results showing large rotations of Corsica⁸⁰ and Sardinia⁸¹ are dismissed by Bayer *et al.*, who note that the islands must first have rotated with Iberia; they attribute the 30° palaeomagnetic declination change in Corsica to this Iberian rotation and state that the larger rotation of Sardinia is not compatible with their data. But the Permian declinations from Corsica differ from those of the Esterel Massif in Provence⁸⁰, which must also have rotated with Iberia since the north Pyrenean transform cannot be drawn between Corsica and the Esterel in the pre-Miocene reconstruction without destroying the striking geological match^{45,80}. Thus the palaeomagnetic data indicate that the islands have rotated with respect to southern France.

We consider the interpretation of the magnetic anomalies to be open to some doubt because of the low amplitude and ambiguous pattern of the anomalies and the inherent problem of correlating the indistinct magnetic profile between anomalies 5 and 6 (10–20 m.y.—the probable age of the Corsica-Sardinia movements) across transform faults. In view of the apparent absence of well developed symmetrical anomaly patterns in marginal basins⁸² particular caution should be exercised in interpreting the anomalies of the western Mediterranean, which shows a number of the characteristics of marginal basins. Herron *et al.*⁸³ emphasise that completely erroneous interpretations can result from incautious use of marine magnetic data. Careful re-examination of both the palaeomagnetic results and the marine magnetic data from the western Mediterranean is clearly necessary.

We thank I. W. D. Dalziel, E. Giannini, W. C. Pitman III, and R. Selli for reading the manuscript, and A. Lazzarotto, M. Manzoni and E. Zarudski for discussions. This work was supported by a NATO Research Grant, a Consiglio Nazionale delle Ricerche Grant, the Industrial Associates of Lamont-Doherty Geological Observatory, and the National Science Foundation (Earth Sciences Section). We are grateful to a referee for directing our attention to ref 79.

Size and folding of the messenger for phage T4 lysozyme

Bernice Ricard* & Winston Salser

Biology Department and Molecular Biology Institute, University of California, Los Angeles, California 90024

The existence of non-random base pairing in T4-specific mRNA is supported by the nuclease digestion patterns of the messenger for phage T4 lysozyme. Under conditions which denature RNA, the nuclease nicked lysozyme mRNA recovers its activity. This behaviour can be explained by a model in which secondary structure controls initiation at existing ribosomal attachment sites.

We have reported techniques for assaying the biological activity of lysozyme messenger RNA in an *in vitro* system¹, and by use of this technique were able to show in preliminary studies^{2,3} that the lysozyme mRNA activity is found in molecules much larger than the lysozyme structural gene alone.

We now show that lysozyme mRNA activity extracted from infected cells occurs in molecules of several discrete sizes. The lysozyme messenger activity of the larger molecules can be destroyed by treatment with T1 RNase *in vitro*. These inactivating cleavages can occur at specific locations outside the structural gene for lysozyme as shown by the fact that, on heat disaggregation, biological activity (for lysozyme synthesis) is recovered in smaller molecules of discrete size classes. We have previously shown by several independent methods that T4-specific mRNAs contain a large amount of highly ordered base-pairing (submitted for publication.) The experiments described here provide further evidence that T4 mRNA molecules have a well defined secondary structure and we discuss the implications of this evidence for processing of bacteriophage mRNA molecules *in vivo* and for control of translation by mRNA secondary structure.

Translation of lysozyme mRNA fragments

RNA extracted 25 min after infection of *E. coli* B⁺ with phage T4D+ can code for lysozyme synthesis in an *in vitro* system^{1,2}: Fig. 1 shows that digestion with increasing amounts of RNase T1 progressively destroys this ability. To analyse the effects of such digestions on the sizes of the surviving lysozyme mRNA molecules, we have sedimented such preparations on sucrose gradients (Fig. 2). Before nuclease treatment, the RNA was heated at 80° C for 2 min in a low ionic strength buffer containing 0.01 M EDTA, 0.01 M Tris-Cl, pH 7.4 (measured at room temperature), then quick-cooled. The purpose of this procedure, 'heat disaggre-

gation', was to dissociate any aggregates and to reveal any pre-existing 'hidden breaks'. The preparation was then sedimented either without digestion (Fig. 2a), with digestion (Fig. 2b and d), or with digestion followed by a second heat disaggregation (Fig. 2c and e).

In the undigested control sample (Fig. 2a), lysozyme mRNA activity sediments in discrete multiple peaks. Other experiments involving sedimentation in denaturing solvents indicate that active lysozyme mRNA exists in a number of discrete size classes (our unpublished results). Although RNase T1 digestion inactivates the lysozyme mRNA, the activity has a sedimentation profile similar to the control and, in particular, there is no indication that activity is shifted to slower sedimenting peaks (compare Fig. 2b and d with Fig. 2a).

This is the result expected if lysozyme mRNA is tightly folded with a great deal of base pairing. In such a situation, many of the single-strand breaks would be masked so that a lysozyme mRNA molecule containing several nuclease cleavages could be held together by base-pairing, and sediment as a single unit. The results in Fig. 2c and e show that the nuclease-treated molecules do contain hidden breaks: if the nuclease treatment is followed by a second heat-disaggregation these breaks are revealed and the lysozyme mRNA activity is found in smaller fragments sedimenting at about 13S and 18S (compare Fig. 2c with Fig. 2b and Fig. 2e with Fig. 2d). This suggests that the lysozyme mRNA has a well-defined secondary structure in which a small number of very susceptible regions ('hotspots') are preferentially cleaved. If this were not the case, then we would expect the nuclease treatment to yield a broad distribution of fragment sizes with no definite peaks.

Prolonged heating at 80° C destroys lysozyme messenger activity (unpublished data of B. R.). For our heat disaggregation steps, we have used very short heating times to minimise the amount of thermal inactivation. Since Möller and Boedtker⁵ have suggested that heating causes chain breaks, there remained the possibility that thermal chain breaks might explain some of our results. To test this, we have investigated the effect of heating for various lengths of time on the sedimentation pattern. The results show that the main effect of heating is to disaggregate and reveal hidden breaks: the changes in sedimentation pattern which do occur on heating occur very rapidly and are independent of the time of the heat treatment. Thermal breaks, if they occur, should continue to accumulate throughout the heat treatment. After 10 min of heat treatment, which inactivated 74% of the lysozyme messenger activity, there was no indication of thermal breaks in either the sedimentation profile of lysozyme mRNA activity or in the ultraviolet absorption profile of

* Present address: Institut National de La Recherche Agronomique, 33 Pont-de-la-Maye, France.

FIG. 1 130 μ g RNA, extracted either 5 min (●) or 25 min (X) after infection of *E. coli* B⁸ with T4D⁺, at a concentration of 4.8 mg ml⁻¹ was treated with RNase T1 in 0.2 M NaCl, 0.02 M magnesium acetate, 0.05 M Tris-Cl, pH 7.5, in the presence of 50 μ g ml⁻¹ bovine serum albumin (BSA). The largest enzyme to substrate concentration was 1/130,000. After a 10 min incubation at 37° C, EDTA was added in stoichiometric amounts to the Mg²⁺ and the RNA tested in a protein synthesising system *in vitro*.

rRNA. Apparently, most of the thermal inactivation of mRNA which we see must be due to some process which is considerably more rapid than thermal chain breakage, although much slower than heat disaggregation.

Heating activates nicked mRNA

Not only does heat disaggregation cause nuclease-treated lysozyme mRNA activity to shift from rapidly sedimenting complexes to smaller fragments, but also some of the lysozyme messenger activity which was originally lost in the nuclease treatment is recovered (Fig. 2). If we take the original lysozyme messenger activity to be 100%, then the preliminary heat disaggregation reduces the activity to 72%. Subsequent nuclease treatment at an enzyme to substrate ratio of $1:3.2 \times 10^6$ (w/w) causes the activity to decrease to 40% of the original. But a second heat disaggregation causes a 1.4-fold increase in the activity, to 56% of the original. With twice as much nuclease the enzyme activity drops to 21%, but the second heat disaggregation causes a 1.55-fold increase in activity, to 32.5% of the original activity.

These increases in enzyme activity are even more impressive when we consider that the normal effect of the heat treatment alone is to cause a roughly 21% inactivation of messenger activity (unpublished results of B.R.). Corrected for this factor the 1.4-fold activation noted above would be a 1.77-fold increase in activity and the 1.55-fold activation would be a 1.96-fold increase in activity. The stimulation of ability to make active lysozyme resulting when nuclease-treated mRNA was disaggregated was confirmed in other experiments involving heat treatments and immediate assay without sedimentation on sucrose gradients. One sort of model which can explain this type of result is shown in diagrammatic form in Fig. 3. In this hypothetical model it is

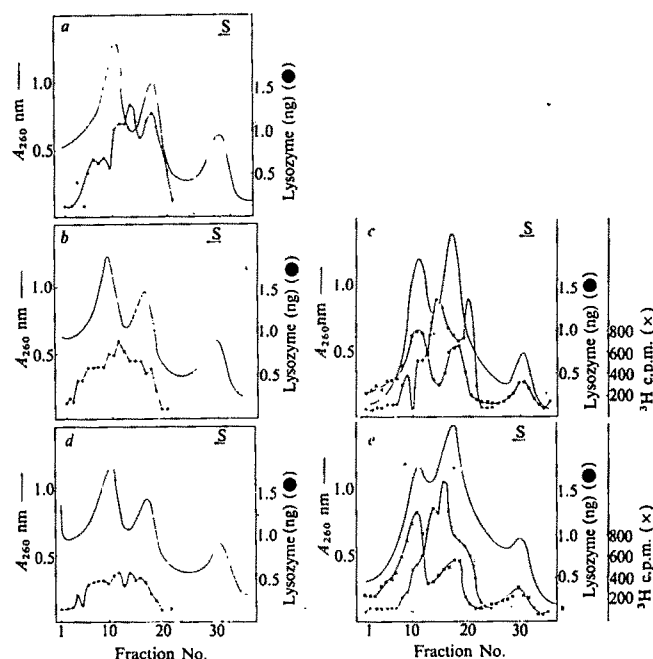

FIG. 2 a, One mg 25 min RNA was heat disaggregated, adjusted to 1 ml in 0.1 M NH₄Cl, 0.01 M ammonium acetate, pH 4.6 and layered on a 36 ml 5–20% sucrose gradient made with RNase-free sucrose in the same buffer. Centrifugation was in a Spinco SW27 rotor at 27,000 r.p.m. for 17 h at 4° C. Fractions of 1 ml were collected and the RNA was precipitated with 2 volumes cold ethanol and 0.1 volumes of 3 M sodium acetate, pH 5.1. The RNA was left at –20° C overnight and the precipitated RNA was pelleted in a clinical centrifuge at top speed. The pellets were allowed to drain for 1–2 h at 4° C and then were dissolved in 50 μ l of sterile, doubly distilled water. A sample of 25 μ l was assayed for lysozyme mRNA activity. The recovery of activity was 72%. Note that in a, as well as in b and d, in which there was only a single heat disaggregation step, there is still some aggregation of rRNA (as shown by ultraviolet-absorbing material sedimenting faster than 23S). We believe that the sedimentation pattern which we observe for the lysozyme mRNA activity is not due to aggregation since the peaks observed after heat disaggregation are similar to those observed during sedimentation in denaturing solvent (DMSO gradients) or when the mRNA has been partially purified before centrifugation so that aggregation with rRNA cannot occur.² In any case, the most important conclusions which we wish to draw are based on changes in the sedimentation profiles of active lysozyme mRNA after the various treatments and these conclusions are largely independent of whether some aggregation is occurring under the sedimentation conditions used. —, $A_{260\text{ nm}}$; ● — ●, ng lysozyme synthesised. b, One mg 25 min RNA which had been heat disaggregated was digested with RNase T1 as in Fig. 1 and layered onto a sucrose gradient without further heat treatment. The enzyme to substrate ratio was $1:3.2 \times 10^6$. After sucrose gradient analysis the recovery of activity was 40% of the original. —, $A_{260\text{ nm}}$; ● — ●, ng lysozyme synthesised. c, One mg 25 min RNA was heat disaggregated and digested with RNase T1 as in (b). Then, to unmask hidden breaks, the RNA was precipitated (by adding 2 volumes ethyl alcohol and 0.1 volumes 3 M sodium acetate, pH 5.1 and centrifuging after 30 min at –20° C), resuspended in 0.5 ml 0.01 M Tris-Cl, pH 7.4, 0.01 M EDTA, and again heat disaggregated. The RNA was then layered onto a sucrose gradient and centrifuged as in (a) with ³H-labelled stable RNA added to provide sedimentation markers. The recovery of activity was 56% of the original. —, $A_{260\text{ nm}}$; ● — ●, ng lysozyme synthesised; X—X, ³H-labelled stable RNA markers. d, One mg 25 min RNA was heat disaggregated, then digested with RNase T1 at an enzyme to substrate ratio of $1:1.6 \times 10^6$. After sucrose gradient analysis, the recovery of activity was 21% of the original. —, $A_{260\text{ nm}}$; ● — ●, ng lysozyme synthesised. e, One mg 25 min RNA was heat disaggregated and digested with RNase T1 as in (d), then reheated in low salt to unmask hidden breaks and centrifuged with ³H-labelled stable RNA markers as described in (c). The recovery of activity was 32.5% of the original. —, $A_{260\text{ nm}}$; ● — ●, ng lysozyme synthesised; X—X, ³H-labelled stable RNA markers.

FIG. 3 Model showing how heating could reactivate nuclease-inactivated mRNA by exposing base-paired ribosomal attachment sites.

imagined that the rapidly sedimenting lysozyme messengers contain (at least) two ribosomal attachment sites, A and B. Lysozyme synthesis is carried out by ribosomes which attach at ribosomal attachment site A, which is exposed, and continue on into the lysozyme cistron. Ribosomes cannot attach at site B because it is in a base-paired configuration. RNase, by cleaving the loop at C prevents the ribosomes from continuing from site A into the lysozyme cistron but ribosomal attachment site B is still blocked by base-pairing. This nuclease-treated mRNA is consequently incapable of directing lysozyme synthesis. By heat disaggregation, however, a small mRNA fragment is liberated which can be translated to yield lysozyme since ribosomal attachment site B is no longer masked by base-pairing.

Processing of mRNA?

Aggregation artefacts cannot explain the fact that the lysozyme mRNA activity extracted from T4-infected cells sediments with a definite peak at about 18S and a shoulder at about 13S (Fig. 4). Corresponding peaks occur under conditions which prevent aggregational artefacts (sedimentation in denaturing solvents or after removal of the stable RNA species) and in dimethyl sulphoxide about 39% of the mRNA activity sediments even faster than the main peak (1,700 nucleotides long, our unpublished results). Since all of the lysozyme mRNA activity is known by several criteria to come from a single structural gene⁹, we are forced to one of two possible conclusions. The first possibility is that the primary transcripts are themselves made in a variety of sizes, either because RNA polymerase transcribes lysozyme

mRNA from a number of different initiation points or because transcription stops at a number of 'partial' termination sites. The second possibility is that the lysozyme mRNA is transcribed as part of a very large molecule, at least 3,000 nucleotides long, and that all the smaller species are produced by endonucleolytic cleavages. Such cleavages could occur *in vivo*, in which case they represent natural mRNA processing steps, or they could occur during the extraction of the messenger (although this is carried out under conditions—sodium dodecyl sulphate, hot phenol—which should minimise nuclease action).

Of course the possibilities above are not mutually exclusive and each could play a role. Of the two we favour the second (processing type cleavage of a large precursor molecule) since the same size (13S and 18S) fragments can be obtained *in vitro* from the large mRNA molecules by RNase T₁ digestion.

Attempts to activate 5' lysozyme mRNA

As previously reported, mRNA extracted 5 min after T4 infection of *E. coli* (5' mRNA) is not competent for lysozyme synthesis in an *in vitro* protein synthesising system². Nevertheless, both hybridisation⁷ and transformation⁸ experiments have demonstrated that lysozyme mRNA is physically present at 5 min. The presence of factors early in infection which might inactivate early lysozyme mRNA and the possibility that the 'early' ribosomes are incompetent have been ruled out already². Our present experiments indicating that secondary structure can prevent translation of lysozyme mRNA support the idea that lysozyme mRNA might always be made in a form inactive due to its secondary structure. Late in infection such a lysozyme mRNA could be activated, perhaps by cleavage of a fragment which exposes the ribosomal attachment site or by modification of the structure.

With this in mind, we attempted the following experiments to activate 5' mRNA. To determine whether we could activate early lysozyme mRNA by adding some factor produced late in infection we replaced the S30 extract from uninfected *E. coli* with an S30 extract prepared from cells infected for 30 min with T4em74, a T4 mutant carrying a nonsense codon in the lysozyme *e* gene. No lysozyme synthesis was obtained with 5' mRNA even at the magnesium concentration which

FIG. 4 Two mg RNA extracted with sodium dodecyl sulphate and hot phenol from *E. coli* infected with T4D¹ was layered onto a sucrose gradient, as described in Fig. 2. The recovery of activity was 96%. —, A_{260 nm}; ● — ●, ng lysozyme synthesised.

gave optimal synthesis with the late mRNA control. Attempts were also made to activate the early lysozyme mRNA by carrying out the *in vitro* synthesis at elevated temperatures or by limited digestion of the early mRNA with RNase T1. The RNase T1-treated material was tested both with and without a subsequent heat disaggregation. No evidence for activation of 5' lysozyme mRNA was obtained even though the controls carried out with 25' mRNA indicated that we had succeeded in covering the optimal range of each one of these treatments.

Base-pairing in lysozyme mRNA non-random

It has long been established that the mRNA from the RNA bacteriophages is highly base-paired. Recent work with f2 and R17 RNA suggests that the secondary structure of these molecules is related to translational control^{9,10}. But the RNA phage genomes may be unlike other mRNA species since they are self-replicating and must be capable of folding to fit a spherical virus capsid: their secondary structure might be for instance, a special adaptation to facilitate encapsulation^{11,12}. For this reason we have examined bacteriophage T4 messenger RNAs. Since they are synthesised from a double stranded DNA genome their characteristics may be more nearly typical of other mRNA species.

Our previous experiments utilising several indirect methods (optical studies, partial digestion with single-strand specific nucleases, and sedimentation under denaturing and non-denaturing conditions) suggested that T4-specific mRNAs contain a considerable amount of base pairing (submitted for publication). But Fresco *et al.*¹³ have asserted that even random RNA sequences may contain as much as 60% base pairing. If the random base pairing structures they proposed are compared directly with those derived from direct sequencing of 16S rRNA^{14,15} it becomes immediately obvious that the random structures should have much lower melting temperatures, less cooperativity in their melting curves and greater sensitivity to single-strand-specific nucleases. Since our previous experiments show that T4 mRNAs are very similar to rRNA in all these regards, (and unlike

random copolymers, our data in preparation) it seems clear that chance base pairing cannot explain the secondary structure observed.

The idea that the secondary structure of lysozyme mRNA is highly ordered is further supported by our finding that nuclease treatment yields active fragments in discrete size classes. The mRNA molecules would be expected to exist in a large number of different configurations with similar stabilities if only random base pairing were involved. If so, nuclease digestion of exposed single stranded regions should not have given the discrete peaks of activity observed in Fig. 2c and e.

PHYSICAL SCIENCES

Difficulty of interstellar radio communication

IN 1959 Cocconi and Morrison¹ suggested that the hyperfine transition of atomic hydrogen at 1,420.405 MHz is the uniquely rational choice of frequency to use in attempts at interstellar communication. Since then other rational choices have been put forward: for example, the first or second overtones of this frequency^{2,3} or the frequency of one of the hydroxyl transitions at 1,612, 1,665, 1,667 and 1,720 MHz^{3,4}. Very recently Drake and Sagan⁵ have argued ingeniously in favour of yet two further frequencies. Unfortunately, none of the rational choices may now be treated with confidence as the correct one. This magnifies the difficulty of the problem.

By an understandable process of self-selection, writers on the subject of interstellar radio communication tend to be at

least cautiously optimistic. The view of the perhaps rashly pessimistic should not be allowed to suffer by default.

Following Drake and Sagan⁵ I shall for definiteness make what they refer to as "the rather optimistic assumption" that the number of stars n_s which must be searched is about 10^6 , which corresponds to the number of civilisations N in the Galaxy being about 10^5 and to the likely distance to the nearest civilisation being several hundred (say 300) light years. In the steady state⁶

$$N = RL \quad (1)$$

where R is the annual rate at which civilisations evolve and L is their average lifetime. It has been estimated³ that R may be as high as 10^{-1} yr^{-1} , in which case equation (1) may be written

$$N = 10^{-1}L \quad (2)$$

and for N to be 10^5 would require L to be 10^6 yr .

The probability of a transmitting radio telescope on a

distant planet (civilisation X) and a receiving radio telescope on Earth (civilisation E) being directed toward one another at corresponding times is minute. Sophisticated survey schemes may be envisaged but may be ignored in the context of an order of magnitude calculation.

To favour the feasibility of the civilisations making radio contact, I shall suppose that both X and E take their orbital motion around their parent star accurately into account, and I shall suppose further that the presumably technically very much more advanced X measures the radial velocity of every star in the survey to within $\pm 0.01 \text{ km s}^{-1}$, as seems possible⁷, and also takes this into account. At the frequency of the hyperfine line of atomic hydrogen (which for definiteness I shall use for illustrative purposes) the uncertainty in the Doppler shift would then be about 10^2 Hz . To keep the number of channels as few as possible I shall suppose that X transmits on a band of this width. The power radiated would have to be high. For example, if the dishes of both radio telescopes were 300 m in diameter, some 10 MW would be needed to reach a distance of 300 light years with a strength equal to sky noise at a temperature as low as 10 K. Finally, to favour the feasibility of the venture under consideration yet again, I shall suppose that E guesses X's general procedure (and is content to use a single channel).

The times required for X and E to survey n_s stars systematically are respectively

$$J(X) = n_s n_c \tau(X) \quad (3)$$

and

$$J(E) = n_s \tau(E) \quad (4)$$

where n_c is the number of channels regarded as rational choices and where $\tau(X)$ and $\tau(E)$ are the X and E times per star per channel.

Sending a significant signal takes longer than detecting the existence of a signal, so

$$\tau(X) > \tau(E) \quad (5)$$

and hence

$$J(X) > J(E) \quad (6)$$

Accepting equations (5) and (6) it is a straightforward task to prove that during any complete survey of the n_s stars by X the probability that two dedicated radio telescopes would be directed towards one another at corresponding times when using the same channel is

$$P = \tau(X)/J(E) \quad (7)$$

provided

$$\tau(X) < J(E) \quad (8)$$

Omitting the time of passage between X and E, the time before radio contact is likely to be established is therefore around

$$T = J(X)/P \quad (9)$$

$$= n_s^2 n_c \tau(E) \quad (10)$$

Subject to condition (8) being satisfied, T is independent of $\tau(X)$ so that quite an extended message could in principle be transmitted.

In view of the suggestions referred to in the first paragraph, I think it not unreasonable to assign the value 4 to n_c , in which case (10) may conveniently be written

$$T = 10^5 \tau(E) \text{ yr} \quad (11)$$

where $\tau(E)$, which of course includes the time lost in changing from one star to the next, is measured in s. It was the

practice to observe a band 100 Hz wide for 60 s in Project Ozma. Though $\tau(E)$ could certainly be made much briefer than this, it is apparent from equation (11) that T is a depressingly long time. The position would naturally be eased if X and E were each sufficiently concerned to use a number of dedicated radio telescopes. Some adverse factors not mentioned here have to be taken into consideration (see ref. 8).

Agreeing with the penultimate sentence of the previous paragraph the referee has argued that there is no real problem because X is likely to use as many as 10^5 dedicated radio telescopes, the cost being of little moment owing to X's highly advanced technology. This is indeed conceivable (though if the population of X were, say, 10,000 million it would correspond to one dedicated radio telescope per hundred thousand inhabitants). I think, however, that nothing can be said with confidence about the true wealth of X, which is determined by many complex factors such as the balance between the effects of technical progress and depletion of natural resources. Again I think it is open to question whether X's interest in galactic anthropogeny would be deep and long lasting.

An entirely different time is now of relevance. How long would a search project be continued in the absence of success? I am sceptical that it would be continued for even a century but adopting a very favourable view I shall suppose that it would continue for 500 yr. Furthermore, I shall suppose that the complete failure of one search project would not prevent another being initiated at some later date. Repeated failures would make fresh starts ever more difficult and 10^4 yr seems to me a very generous upper limit to the average total duration of the searches, that is to the average lifetime of the civilisation in communicative phases. This increases the effective extent of our isolation.

Referring to equation (2) it may be seen that a consequence is that the number of communicative civilisations in the Galaxy is at most 10^3 , from which it follows that the likely distance to the nearest is at least several thousand light years. Perhaps most serious, the value of the right side of formula (11) for the time before contact between a pair of dedicated radio telescopes is likely to be made becomes $10^7 \tau(E)$ years or, more probably, very much longer (some of the favourable suppositions made in the derivation of the formula being now untenable). The prospect is unpromising.

CH₄ and CH₂ in comets

MANY of the simple radicals observed in cometary spectra, for example OH and NH, probably originate as dissociation products of more stable parent molecules such as H₂O and NH₃. Ip and Mendis¹ have recently discussed the possibilities of observing H₂O in Comet Kohoutek (1973f). If CH₄ exists in significant abundance in comets, it could be a parent of observed CH and CH⁺. It is difficult to observe CH₄ directly but a rather specific though indirect means of detecting its presence is suggested.

Dissociation of CH₄ by monochromatic photons at the wavelength of hydrogen L α (1,216 Å) results in

(see ref. 2). Fluorescence, resulting from the radiative decay of the excited CH₂ by emission in the $\tilde{b}^1B_1 - \tilde{a}^1A_1$ system, accompanies this process. Hydrogen L α is the strongest emission line in the solar spectrum and its intensity at any point in the orbit of a comet can be calculated. A search for the lines of CH₂ ($\tilde{b}^1B_1 - \tilde{a}^1A_1$) lying between wavelengths of 5,000 Å and 9,000 Å (refs. 3 and 4) may be a useful, specific probe for both CH₄ and CH₃.

It is safe to assume that there is no other process capable of exciting the \tilde{b}^1B_1 state of CH₂ efficiently, and that the state is unlikely to be deexcited by collision before radiating. The total emissivity in lines of CH₂, $E(\text{CH}_2)$, is related to the concentration (cm⁻³) of CH₄, $n(\text{CH}_4)$ (cm⁻³), and to the solar L α flux, $\Phi_{L\alpha}$, according to

$$E(\text{CH}_2) = \Phi_{L\alpha} n(\text{CH}_4) \sigma(\text{CH}_4) \text{ photons cm}^{-2} \text{ s}^{-1}$$

where $\sigma(\text{CH}_4)$ is the cross section of process (1), estimated to have a maximum value of about 1×10^{-20} cm² (ref. 2). At a distance of 1.0 AU from the Sun, $\Phi_{L\alpha} \cong 3 \times 10^{11}$ photons cm⁻² s⁻¹ (ref. 5), and therefore

$$E(\text{CH}_2) \cong 3 \times 10^{-9} n(\text{CH}_4) R_{sc}^{-2} \text{ photons cm}^{-2} \text{ s}^{-1}$$

where R_{sc} is the distance (AU) of the comet from the Sun. The total flux in the lines of the $\tilde{b}^1B_1 - \tilde{a}^1A_1$ system of CH₂ received at the Earth is given by

$$\Phi(\text{CH}_2) \cong 8 \times 10^{-10} R_{sc}^{-2}$$

$$\int n(\text{CH}_4) dl \left(\frac{R_{coma}}{R_{sc}} \right)^2 \text{ photons cm}^{-2} \text{ s}^{-1}$$

The integration is along the path length over which CH₄ is in gaseous form in the coma, R_{coma} is an average size describing the region of emission and R_{sc} is the Earth-comet distance.

For Comet Kohoutek (1973f) near perihelion, $R_{sc} \cong 0.15$ AU, $R_{coma} \gtrsim 10^{11}$ cm and $R_{sc} \cong 1.0$ AU = 1.5×10^{13} cm, and therefore a flux at the Earth in the CH₂ lines

$$\Phi(\text{CH}_2) = 2 \times 10^{-12} \int n(\text{CH}_4) dl \text{ photons cm}^{-2} \text{ s}^{-1}$$

An effective column density $\int n(\text{CH}_4) dl$ of 10^{15} cm⁻² should produce detectable CH₂ emission even if it is distributed over 100 lines of roughly equal strength: approximately 2×10^3 photons s⁻¹ per line, assuming a 60 inch telescope with a spectrometer or spectrograph such that the quantum efficiency for the complete system is 0.01. The vacuum wavenumbers of the CH₂ lines which have been observed in absorption are given by Herzberg and Johns⁴.

I thank Professor A. Dalgarno and Mr L. E. Goad for discussions.

Sixth radio outburst of Cygnus X-3

FIVE large outbursts of radio emission from Cygnus X-3 have been reported, (refs 1-3 and V. A. Hughes, unpublished). We present here observations of a sixth, which occurred in June and July 1973. The observations were made using the 46-m telescope of the Algonquin Radio Observatory at 10.6 GHz (bandwidth ~ 100 MHz, system temperature ~ 120 K). A total of 60 flux density measurements, each providing 7 min of integration time on the source, were made during the period June 25 to July 6, 1973. These observations were taken at sporadic intervals during our programme of measuring early-type emission-line stars, and the observing technique described in ref. 4 was used.

In Table 1 and Fig. 1 we give the measured flux density values for Cygnus X-3. Allowance has been made for the effects of confusion, using data provided by P. C. Gregory which had been derived from observations of the first recorded outburst. The error bars are standard deviations representing the combined effect of random noise (which in many cases was large, due to poor weather conditions), variations in calibration level, and several smaller factors such as the uncertainty due to confusion effects. The flux density scale is based on 3C123 = 7.92 f.u., and 3C274 = 37.1 f.u.

The decay of the sixth outburst was exponential. An exponential decay was also noted for burst 1 (ref. 5), and our analysis of the published data for the other outbursts

FIG. 1 Measured flux densities of Cygnus X-3 at 10.6 GHz during the sixth outburst.

indicates similar behaviour, suggesting that an exponential decay is a general characteristic of Cygnus X-3 radio bursts. This is clearly incompatible with source models involving simple adiabatic expansion, which predicts a power-law decay⁶.

We have developed an alternative model for the Cygnus X-3 radio source. We propose that ambient gas affects the radiation from the synchrotron source in two ways: (i) A high density gas occupies part of the path traversed by the synchrotron-emitting electrons, causing them to lose energy primarily by bremsstrahlung losses. This would explain the exponential decay of the radio bursts, as was suggested⁵ for the first outburst. (ii) Each outburst is accompanied by an expanding cloud of ionised gas which surrounds the synchrotron source. If the cloud is initially optically thick at a particular frequency, then the synchrotron source will be obscured. As the gas expands, the decreasing

free-free optical depth will result in an increase of the observed intensity. Further the observed outburst will be progressively delayed at lower frequencies. In that case, the form of the rise would depend primarily on the characteristics of the expanding cloud. But if the cloud is optically thin at a particular frequency, then the synchrotron source will be unobscured, and the outburst will be observed simultaneously at all higher frequencies. In that case the form of the rise depends directly on particle injection in the synchrotron source.

This model explains several features of the observed bursts: the exponential decay, the time delay at lower frequencies of some bursts, and the simultaneous rise over a wide range of frequencies of other bursts.

It is interesting that analyses of Cygnus X-3 based on its radio spectrum⁷ and X-ray characteristics⁸ have also led to models which require the presence of a thermal absorbing cloud.

We thank Mrs Molly Morrow for assistance. This work was supported in part (C.R.P.) by an operating grant from the National Research Council, Canada, and in part (P.A.F.) by the President's Fund of York University. The Algonquin Radio Observatory is operated by the National Research Council, Ottawa, Canada, as a national radio astronomy facility.

Distribution of late Pleistocene aeolian deposits in eastern and southern England

THERE has been much recent interest in the possible existence of widespread aeolian deposits in Britain. In southern England brickearths at Pegwell Bay¹⁻³ (TR36) and elsewhere⁴ have been interpreted, although without mineralogical confirmation, as extensions of European loess. Silt, in excess of that which could be derived from weathering of the substrata and generally considered loessial, is found in many British soils⁵⁻¹⁰ but it is not ubiquitous. For example, although it occurs in soils on Chalky Boulder Clay in Essex¹¹, on the same till in central East Anglia and on the Chalk of the Breckland and north-west Norfolk it is replaced by sand.

The lithology, and hence likely weathering products, of the Chalky Boulder Clay are very uniform over a large area of eastern England¹². The till thus provided a unique substratum on which to survey the distribution of sandy and silty surface deposits. The patterns were later traced onto

TABLE 1 Soil provinces in East Anglia and East Midlands

other formations and into other areas. The survey is summarised here and will be described in detail elsewhere.

East Anglia and east Midlands: The top 4 cm of the soil were sampled at least once in every 10 km grid square containing Chalky Boulder Clay in East Anglia and, at a slightly lower density, in the East Midlands with appropriate replication (190 samples). To minimise effects of solifluxion or downwash each sample was taken from the top of an interfluvium, normally the highest point in the square.

Mechanical analysis of the carbonate-free fraction < 2 mm of every sample showed that the soils were unlike any conceivable weathering residue of the under-lying Chalky Boulder Clay and could be grouped into four provinces defined by the unimodal or bimodal form of the composition curves and by peak particle diameters (Fig. 1 and Table 1). Soils of province I are clearly enriched in silt, those of III in sand and those of II and IV in silt and sand. Once recognised on the lithologically uniform till the provinces were traced across interfluvium on Cretaceous sands, Chalk, Tertiaries, Norwich Brickearth and the March and Observatory Gravels of Cambridgeshire; and onto flat sites on the Terrace

Gravels of the Ouse, Cam and Lark (104 samples). Their distribution is shown in Fig. 2; they transgress geological boundaries, are unrelated to land-form or altitude and, except between I and II, are sharply separated.

There is a tendency, shown by differences between the means and modes, for peak diameters in the sand grades to decrease southwards, although ranges are similar (Table 1); no east-west trends have been observed. Peak diameters in the silt grades show no consistent geographical relationships.

Heavy mineral counts on the fraction 105 to 63 μm (65 samples) showed that the soils of Province III are the least like the till (Table 2), being significantly different in total heavy minerals ($P < 1.0$) and in opaques, rutile, zircon, epidote, amphiboles and micas. Those of provinces II and IV differ significantly in opaques, zircon and micas, and those of I differ in garnet, rutile, zircon and micas, although only five samples have been examined. Apart from the absence of mica in III there are no qualitative differences between the till and the various soils, suggesting that all the sand grades may have a common ultimate source. Quantitative differences could reflect derivation from different parts of that source or modifications during transport.

Stones in the topsoils cannot be compared directly with those in the till since chalk, the commonest erratic, dissolves in soil formation. But counts of 500 non-calcareous stones at each of 25 sites showed that there are no significant differences between the till and the soils. This suggests, though it does not prove, that surface drifts on the Boulder Clay are not merely the remnant of a later glaciation¹².

The only satisfactory explanation for all these observations is that thin silty and sandy drifts were added to the surface and incorporated by processes such as frost-heaving and biological mixing. Their wide persistence across differing substrata, their invariable occurrence on the highest interfluvium and, within each province, the uniformity of peak particle diameters (with values typical of blown sands and loess) support aeolian origins and argue against deposition by water, ice or ablation.

In province III, the peak diameters, low silt contents and absence of micas indicate that the soils are probably derived from blown sand more or less mixed with the substrata (Fig. 1c). Since the Breckland falls clearly in this province it now seems probable that the sandy-chalky drift and soils of that area are derived ultimately from blown sand rather than a local sandy till¹³.

In provinces I, II and IV, loess is the likely source of the widespread silt since heavy minerals in the fraction 63 to 20 μm are similar throughout. Province IV (46 sites) includes a smaller area (six sites) of 'cover loam' soils reported to contain loess from Devensian deposits¹⁴.

In provinces II and IV the bimodal composition must result from deposition of both sand and silt. Since peak particle diameters in the mineralogically similar sand fractions are comparable in II, III and IV, although with a small trend in mean values, these provinces are probably all parts of one blown sand complex. As pointed out below, the relationship to topography supports this conclusion. The

† Percentage by number of total heavy minerals.

‡ Percentage by number of non-opaque heavy minerals.

suggestion that the sand component in the cover loam soils was derived from subjacent deposits¹⁴ may be locally true but is not generally valid as the provinces cross some formations which could not provide such material.

Lincolnshire and Yorkshire: Mechanical analysis of the topsoils from 55 interfluvial sites in Lincolnshire and east Yorkshire showed that province III extends beyond the Fens and continues across the Humber. The heavy minerals in these areas and those of III in East Anglia are not significantly different (Table 2). Just as the Breckland seems to be a thick accumulation of the sands of this province in Norfolk, so the 'cover sands' south of Scunthorpe (SE91) appear also to be mechanically and mineralogically part of it rather than a purely local deposit redistributed from the Trias¹⁵.

The boundary between provinces II and III was traced as far as Sleaford (TF04) (Fig. 2). On the east side of III silt accumulations were found on the Lincolnshire and Yorkshire Wolds (Va and Vb). East of the Wolds other Devensian deposits and alluvium make interpretation difficult but there was no evidence for any extension of province IV at any of the fourteen sites examined.

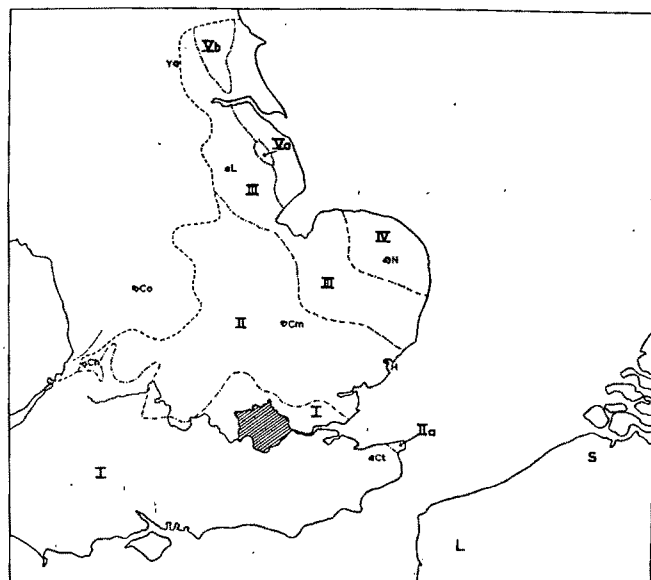

FIG. 2 Distribution of provinces in eastern and southern England. — — —, Province boundaries; — — —, present limits of sampling. Ch, Cheltenham; H, Harwich; Cm, Cambridge; L, Lincoln; Co, Coventry; N, Norwich; Ct, Canterbury; Y, York; S, cover sand zone in Belgium and the Netherlands.

Midlands and southern England: A further 252 interfluvial sites were sampled, on the Boulder Clay and on other formations suitable for the detection of extraneous material. These were granites, serpentine and gabbro; Devonian, Carboniferous and Jurassic limestones; Jurassic clays, the Lower Greensand, Chalk, Clay-with-flints and various gravels. All areas previously shown to contain loessial soils⁵⁻⁹ were included. Sampling density was lower than in East Anglia and unsuitable substrata excluded many areas, particularly in southern England (Fig. 3).

Mechanical analysis of all samples showed that the boundary between provinces I and II, although not clearly defined, extends westwards to near Cheltenham (SO92) and south-eastwards into Thanet, where there is a small area of soils (IIa) mechanically similar to those of II but with quantitative differences in mineralogy (Figs 2 and 3, and Table 2).

In province I, although their extraneous origin was sometimes uncertain, accumulations of silt with peak diameters ranging from 16 to 50 μm were found in 177 samples (Fig. 3). The conclusion that this persistent silt is loess is supported by heavy mineral compositions of the fractions 105 to 63 μm and 63 to 20 μm . The former is generally closely similar to the same grade in the substratum but the latter is fairly constant over the whole area (Table 3).

Within province I there are locally a few bimodal soils. Although some of their sand fractions are clearly derived from substrata, such as Lower Greensand or remnants of Reading Beds on Chalk⁹, others seem to be definitely aeolian. More intensive sampling might allow this province to be sub-divided.

Peak diameters for the sand fractions of some soils of provinces II, III and IV lie above 210 μm ('coarse' soils), the remainder below ('fine'). The frequency of occurrence of 'fine' soils is unrelated to province boundaries or geographical coordinates but shows a statistically significant tendency to increase with altitude (Table 4).

In East Anglia the long axis of the area of high altitude 'fine' soils lies perpendicular to the boundary between II and III suggesting that these contain the same blown sand complex which has been similarly affected by topography in both of them.

Since there is no relationship between silt grade peak diameter and either geographical position or altitude, it is possible that, whereas during saltation finer sand could better surmount gradients than coarse, silt deposited from suspension was more influenced by local factors such as air turbulence or vegetation.

In East Anglia, the sands of provinces II, III and IV are frequently involuted into the Boulder Clay, presumably by

† Percentage by number of non-opaque heavy minerals

‡ Note the specially high proportion of micas in both fractions of granite soils

§ Barite is locally present as veins in the limestone in this area

The first column under each locality is for the fraction 105 to 63 μ m, the second for the fraction 63 to 20 μ m.

cryoturbation. Sections along the margin of the Breckland show that this was contemporary with that producing the well-known patterned ground¹³ which, being closely related to present topography, is generally regarded as Devensian. The sands must thus be at least as old as the last major periglacialiation in the area. But topsoils typical of Provinces II and III have been traced onto the March and Observatory Gravels and all three Terrace Gravels of the Ouse, Cam and Lark. The youngest of these, the First Terrace¹⁶, has been dated at $19,500 \pm 650$ BP (ref. 17) suggesting a probable maximum age for the sand.

In contrast to the sands, no interfluvial sites are known in East Anglia at which the silt has suffered periglacial disturbance and at Great Blakenham, Suffolk (TM103503) it is clearly younger than the sand: the soil here is bimodal but with increasing depth into the weathered till it becomes more sandy and there are deep sand pockets devoid of silt (Fig. 1e). One may deduce that the sand arrived first, was incorporated by cryoturbation and then covered by silt which was mixed by biological agencies to give the present sandy-silty topsoil. This is the most likely origin of all the bimodal soils for it is difficult to envisage any mechanism by which sand and silt could arrive simultaneously. Explanations for the distribution of provinces and the sharpness of most boundaries can so far be only speculative.

There is further evidence that the interfluvial silts in the south-east are relatively late. In the present study they have been traced by mechanical and mineralogical analysis across interfluvial in Kent into the top of the brickearth at Pegwell

Bay which lies above the highest frost structures^{1,2}. The survival of silt on exposed scarp crests on the South Downs and Yorkshire Wolds also suggests at least some deposition after intense solifluxion ceased⁹. No valid correlations have yet been made between the interfluvial silts and valley deposits in southern England reported as loessial^{4,18,10}.

TABLE 4 Peak particle diameter in relation to altitude

Altitude Feet OD	No. of samples 'Coarse' type	No. of samples 'Fine' type	P
0-300 (0-90 m)	162	117	<0.1
300-600 (90-180 m)	28	56	<0.1
600-900 (180-270 m)	1	13	<0.1

So it seems that the sands of provinces II, III and IV originally arrived before or during the last intense periglacialiation in the Devensian and the silts of I, II and IV later. It is difficult to accept that the latter could belong to the penultimate glaciation as has been suggested for some of the valley brickearths⁴.

Provinces I and III show some geographical relation to the zones of loess and cover sands established in Europe^{20,21} (Fig. 2). Preliminary mechanical analyses and heavy mineral counts confirm continuity between the silts of province I and loess on the Chalk of northern France (Table 3). But because of the general thinness and reworking of the sands of provinces II, III and IV, no valid stratigraphical correlation can yet be made with the thick series of cover sands in Holland and Belgium. This is being studied further.

Geophysical evidence for the intersection of the St Paul, Cape Palmas and Grand Cess fracture zones with the continental margin of Liberia, West Africa

PUBLISHED reconstructions of Gondwana continent¹ (Fig. 1a) show a gap in fit near the junction of the Americas and Africa. To study this critical area, the Unitedge I made geophysical measurements and collected rock samples across the continental margin of Liberia (USGS-IDOE cruise leg 5) in November 1971. Figure 1b indicates the location of the 5,400 km of ship track on a generalised bathymetric map². We shall discuss the data in detail elsewhere. Here we present the evidence for the existence of three fracture zones, two of which have not been reported previously, intersecting the continental margin at the north end of the South Atlantic, which remained closed probably until Cretaceous time. We suggest that Precambrian structures on the African continent controlled the location of these fracture zones. Figure 1c compares gravity and magnetic profiles and interpretations of the seismic profiles for three selected lines (27, 30 and 34) crossing the Grand Cess, Cape Palmas and St Paul fracture zones, respectively.

The bathymetric data (Fig. 1b) indicate that the north-west section of the continental margin of Liberia is narrow, the slope is moderately rough and the average gradient is about 3° (ref. 2). South-eastwards to about 9°30'W (about line 22) the slope gradually becomes smooth and wider and the average gradient is about 1.8°, which suggests depositional outbuilding. The topography of the area southeast of about line 22 reflects the effects of the inferred three fracture zones (the Grand Cess, Cape Palmas and St Paul fracture zones), where locations as indicated in Fig. 1b are interpreted from the magnetic and gravity data. Figures 2 and 3 show the magnetic and gravity profiles normal to the coast and indicate the anomaly correlations over the inferred fracture zones. The anomalies on lines 1 to 21, north-west of the fracture zones, are not discussed here but are shown for comparison. The St Paul fracture zone has been reported previously in

this area by others⁴⁻⁶. The comparison profiles shown for lines 27, 30 and 34 (Fig. 1c) are typical of the other lines crossed by the inferred fracture zones as indicated in Fig. 1b.

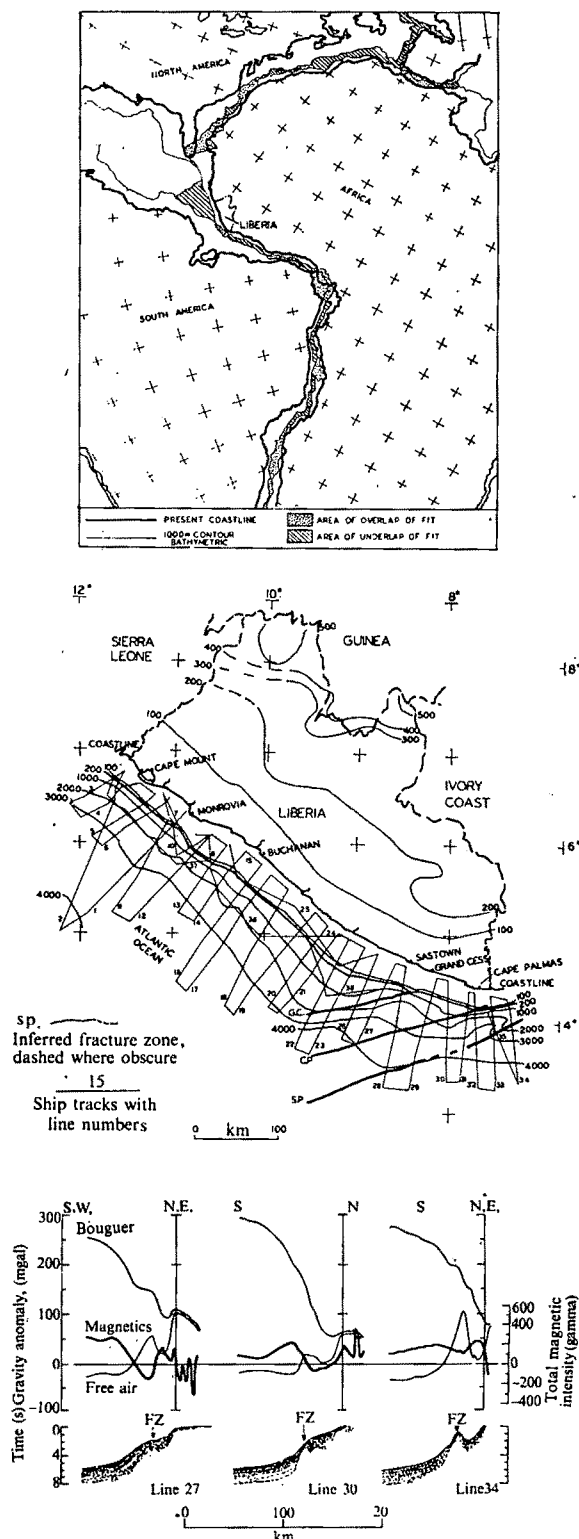

Fig. 1 a, Reconstruction showing predrift configuration of parts of continents around the Atlantic Ocean, taken from ref. 1. Note the good fit in the eastern third of Liberia and the poorer fit in the western two-thirds. Contours in metres. b, Index map showing generalised bathymetric and surface-elevation contours, as well as ship-track lines. Locations of Grand Cess, Cape Palmas, and St Paul fracture zones are indicated, as inferred from magnetic and gravity data. c, Geophysical profiles along lines 27, 30 and 34 crossing the Grand Cess, Cape Palmas and St Paul fracture zones, respectively. Seismic reflection interpretations are shown at bottom in two-way time.

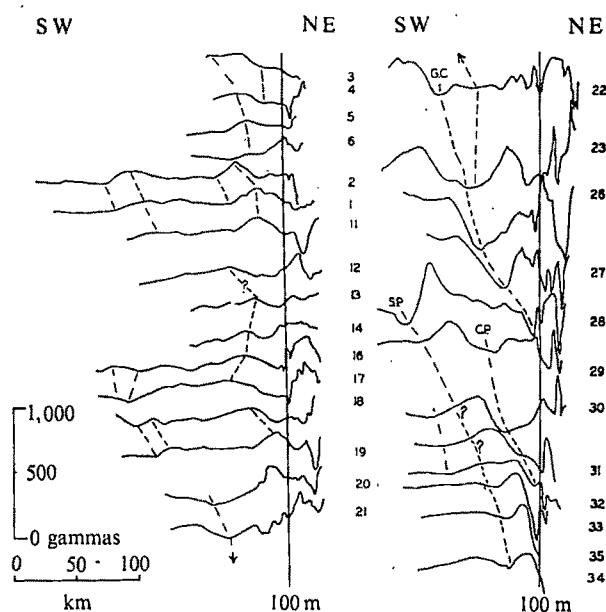

FIG. 2 Magnetic profiles for indicated track lines approximately normal to coast with IGRF removed. Suggested anomaly correlations are indicated. Tics indicate the inferred Grand Cess (G.C.), Cape Palmas (C.P.) and St Paul (S.P.) fracture zones are based on magnetic and gravity data.

We interpret the features labelled as the Cape Palmas and Grand Cess fracture zones on the basis of their similarity in geophysical character to the St Paul fracture zone. The extension of the Cape Palmas and St Paul fracture zones south-west of our ship tracks is based on earlier published magnetic data⁴.

Behrendt and Woterson^{7,8} presented data over the land and continental shelf and compiled a tectonic map based on these data and available geological information. Rock foliation and tectonic features trend east-northeastwards in the Eburnean province of south-east Liberia, as illustrated by aeromagnetic data (Fig. 2). These linear anomalies are asso-

FIG. 3 Free air anomaly profiles for indicated track lines approximately normal to coast. Vertical bars indicate locations of Grand Cess (G.C.), Cape Palmas (C.P.) and St Paul (S.P.) fracture zones as inferred from magnetic and gravity data; horizontal bars indicate 0 mgal.

ciated with isoclinally folded and faulted paragneisses of Eburnean age ($\sim 2,000$ m.y.). Comparison of the trends of the fracture zones (Fig. 1b) with the trends of the magnetic anomalies of Fig. 4 shows that they are similar. The marine magnetic anomalies over the Grand Cess and Cape Palmas fracture zones (Fig. 1c) are continuous into the aeromagnetic anomalies of Fig. 2, although they are of longer wavelength because of greater water depths and depth of magnetic basement on the marine data. The magnetic anomaly associated with the St Paul fracture zone passes out of the surveyed area; this fracture zone intersects the margin of West Africa farther east⁴⁻⁶ (Fig. 1b). We do not imply, from this correlation, that the fracture zones and sources of magnetic anomalies on the continent are the same; the great discordance in ages between the Eburnean province (about 2,000 m.y.) and the time of rifting of Africa and South America during the Cretaceous precludes that. We interpret this coincidence in trends to indicate that the isoclinal folds and faults in the Eburnean province might have provided structural control for the location of the fracture zones developed at the time of rifting. In coastal Liberia the geological evidence of actual faulting that could definitely be said to be syntectonic with rifting is lacking, although work by Francheteau and Le Pichon⁵ suggests this possibility. A fault inferred from aeromagnetic data and confirmed by geologic mapping on land (A. H. Chidester, personal communication) occurs in the area where the Grand Cess fracture zone intersects the shelf. The tectonic map of Liberia⁹ also reveals several structures where the Grand Cess fracture zone intersects the shelf. We do not know the age of these features but they could be related to the fracture zones.

Though now buried, as indicated from the seismic data of Fig. 1c, the three fracture zones reported here have influenced subsequent deposition of sediments and the physiography of the slope and rise. Probably the broadening of the slope between line 13 and 22 (Fig. 1b) is related to the fracture zones, in the manner suggested by Francheteau and Le Pichon⁷ for the fracture zones in the Gulf of Guinea. This area, northwest of line 22, is the area of the gap in the Bullard *et al.*¹ reconstruction and was probably part of the continental margin earlier (at the time of the opening of the North Atlantic) than the area crossed by lines 23 to 35 (which originated at the time of the South Atlantic opening). At the scale of the entire South Atlantic, these fracture zones are very close together; in fact, they all lie easily between the 17° and 19° flow lines about Francheteau and Le Pichon's⁷ early pole of opening. The continuation of these inferred fracture zones into the similar northeast trending magnetic anomalies of the south-east Liberian continental shelf (Fig. 2) led us to conclude that the Precambrian isoclinally folded and faulted metamorphic terrane influenced their orientation and location at the time of opening of the South Atlantic.

Cochran⁹ showed several approximately north trending gravity and magnetic profiles west of our data (from about 15°W to 43°W). He identified the St Paul fracture zone crossing the Atlantic to the South American margin on the basis of its characteristic appearance on these profiles. The profiles on the African side (V2713 and V2604, in particular) and the profile nearest South America (V2502) are similar to those presented here. Just north of the anomaly associated with St Paul fracture zone on Cochran's data, are features we identify as associated with the Cape Palmas and Grand Cess fracture zones as defined here.

Probably the St Paul, Cape Palmas, and Grand Cess fracture zones are Cretaceous in age, at the intersection of the African continental margin, based on available information on the date of separation of Africa and South America (about 140 m.y. ago⁶). Previous interpretations^{7,8} that North America separated from Africa about 176 to 192 m.y. ago northwest of about line 22 (Fig. 1b) would require that the oceanic basement in this area be about 40 m.y. older than that to the

Fig. 4 Portion of aeromagnetic contour map in Sastown area with ship-track lines indicated. Contour interval is 10 and 50 gamma. Inferred location of Grand Cess fracture zone is indicated (G.C.). High amplitude anomalies are indicated in gammas.

south-east of line 22. If the Deep Sea Drilling Project (phase 3 leg 40) were to locate several holes in this area it would test this interpretation.

We thank the scientific staff and crew of Unitedgeo I for support. Our colleagues at Woods Hole and in the Liberian Geological Survey (in particular A. H. Chidester and C. O. Bowin) provided many helpful discussions and criticisms.

Production of copper(I) halide emission spectra by MECA

THE introduction of copper(II) salts into most commonly used flames gives a green emission. Copper halides give a particularly intense emission, which is used in the well-known Beilstein test for halogens. The spectra from all copper salts, however, are very similar, and consist mainly of diffuse CuOH bands in the region 535–555 nm, a CuH band centred around 429 nm, CuO emission bands between 445 and 492 nm and a copper atom line at 327 nm (ref. 1, and Fig. 1). Copper(I) halide bands are also present when copper(II) halides are used, but are weak. The enhanced emission of the halides, therefore, arises mainly from their great volatility and consequent enhanced production of excited CuOH, CuO and CuH molecules, rather than greatly enhanced production of copper(I) halide emission. For this reason, pseudohalides such as cyanide and thiocyanate ions also give positive

Beilstein tests. The copper(I) chloride emission that has been observed in flames, especially when they are very fuel lean², is very insensitive for use in analysis.

Recently, we have developed a new, highly sensitive analytical flame technique named molecular emission cavity analysis (MECA)³. In this technique, the sample is placed in a cavity at the end of a steel rod, and the cavity is positioned in a hydrogen diffusion flame so that the flame gases flow almost vertically past the entrance to the cavity, with a small proportion entering the cavity. The flame also heats the exterior of the cavity. The emission characteristics of many materials placed in the cavity are appreciably different from those obtained by aspirating the sample solution into the flame. When microgram amounts of copper(II) chloride are placed in the cavity, or when traces of hydrochloric acid are introduced into a copper-plated cavity, the emission spectrum is very different from that obtained by aspirating an aqueous copper chloride solution into the flame. The spectra are compared in Fig. 1. Particularly noticeable is the much reduced intensity of the CuH, CuOH and CuO bands, and the greatly enhanced bands which can be attributed to copper(I) chloride emissions. The wavelengths of the main emission peaks are summarised in Table 1. The apparent triplet at the lowest wavelengths corresponds closely, in wavelength and relative intensity, with the main peaks of the D and E systems¹ of copper(I) chloride. Similarly the middle triplet corresponds with the B and C systems, and the longest wavelength triplet with the A system.

Fig. 1 Spectra of CuCl_2 in aqueous solution aspirated into $\text{H}_2\text{-N}_2$ diffusion flame (line drawing) and in the cavity (MECA) in the same flame (solid drawing).

Copper(II) bromide and iodide give significantly different spectra in the cavity. The wavelengths of the main peaks are summarised in Table 1. The copper bromide peaks at 480 nm and above correspond closely to those of the A system of copper(I) bromide, whereas the copper iodide peaks at 509 nm and above correlate well with those of the A system of copper(I) iodide. In all instances, the peaks at 437 nm do not correspond to CuH emissions, which would seem to be the only other possible emitters in this wavelength range.

The emissions can be used to detect nanogram amounts of halides. Other copper salts, such as copper(II) sulphate and nitrate, give no emission in the cavity.

Small amounts of tin(II) chloride or bromide in the cavity produce broad emission bands, with peaks at 440 and 460 nm, and 460, 480, 490 and 495 nm respectively. These do not correspond to the well characterised red SnH and blue SnO emissions but appear to be similar, however, to

TABLE 1 Wavelengths (nm) of major peaks in MECA spectra

* most intense peak.
(relative intensities in parenthesis)

the blue or blue-green emission that appears just at the base of a hydrogen diffusion flame when the tin halide is aspirated, and is therefore probably tin halide emission. No spectral measurements of tin halide emissions in flames, however, have been reported. Similar emissions are obtained from halides of indium, lead, cobalt, cadmium and germanium.

The reason for enhanced halide emission from the cavity has not been completely established. It would seem to result, however, from the limited radical concentration in the flame gases within the cavity, which reduce the formation of non-halide copper species, and the relatively cool cavity surface, which enhances the emission of the emitting species as a result of the Salet phenomenon⁴.

Teardrop shapes for small bubbles and drops moving through Newtonian liquids

In each of the previous observations¹⁻¹¹ of bubbles and drops with pointed tails the continuous liquid has had non-Newtonian characteristics. For Newtonian liquids, the shapes of drops and bubbles have been generally reported to pass smoothly from spherical to oblate ellipsoidal with increasing volume. Here we report observations of teardrop shapes for bubbles and drops in Newtonian liquids over a narrow range of sizes.

The experiments were done in a plexiglass column of cross section 39×32 cm and height 117 cm. The continuous liquid was an aqueous sucrose solution of density 1.393 g cm^{-3} and shear viscosity 12.97 poise. The temperature for all the experiments was 29.5°C . Drops of carbon tetrachloride were injected by pouring from the top surface. Drops of silicone oil and air bubbles were formed under pressure at an orifice at the base of the column. The properties of each of the three systems are given in Table 1. No special precautions were taken to eliminate surface-active contaminants

TABLE 1 Physical properties of the systems

Dispersed fluid	Density of dispersed phase ρ_d (g cm ⁻³)	Viscosity of dispersed phase μ_d (poise)	Interfacial tension σ (dyne cm ⁻¹)	Approximate range of sphere-equivalent diameters over which pointed tails have been observed (cm)
Carbon tetrachloride	1.585	0.0105	34.3	1.13-1.70
Silicone oil	0.92	0.545	53.5	0.68-1.19
Air	0.00126	0.00018	73.0	0.58-0.98

from the liquids studied. In order to characterise the rheological behaviour of the aqueous sugar solution, an extensive series of tests was done with a rheometric mechanical spectrometer and with a Weissenberg Rheogoniometer (model RD-18). No dependence of viscosity on either rate of strain or on time could be observed so long as precautions were taken to ensure constancy of temperature and moisture content. Thus the continuous fluid can be taken to be Newtonian. The dispersed fluids (see Table 1) were also Newtonian.

Tracings of drops and bubbles with a teardrop shape, taken from still photographs, are presented in Fig. 1. Tails are observed only for a limited range of drop and bubble sizes as shown in Table 1. As the drop or bubble size is increased beyond the teardrop range, the tail disappears and is replaced by an indentation or dimple at the rear.

FIG. 1 Shapes of air bubbles, and drops of silicone oil and carbon tetrachloride moving through 70%, w/w, aqueous sucrose solution. a, air bubble; sphere equivalent diameter: 0.73 cm; velocity 3.08 s⁻¹. b, Silicone oil; 1.19 cm; 2.82 cm s⁻¹. c, Carbon tetrachloride; 1.56 cm; 1.80 cm s⁻¹.

Drops or bubbles which were given a teardrop shape by the injection process (for example, if the tail was stretched as a drop pulled away from the injection orifice) or by coalescence tended to retain the teardrop shape whereas those which began as spheres tended to remain so unless they coalesced with other drops or bubbles. In other words, a tail once formed was not retracted but spherical fluid particles in free rise or fall did not tend to form tails on their own. The tails observed were generally less pronounced than those reported by other workers for non-Newtonian liquids. Recently, tailing of a filament of the dispersed liquid has been observed for cases where the continuous fluid is significantly viscoelastic¹¹. No such phenomenon has been observed with the Newtonian liquids used in the present work.

We conclude that teardrop shapes are not restricted to non-Newtonian fluids as has been generally believed. On the other hand, the range over which pointed tails can be observed in Newtonian liquids seems to be small and there is little doubt that thixotropic and viscoelastic continuous liquids lead to more pronounced tails and to phenomena, such as trailing filaments, which do not occur for Newtonian liquids.

We thank Dr I. Patterson and Mr M. Ryan for assistance with the rheometer measurements.

Colonisation of the early ocean floor

THE earliest well documented evidence of macroscopic life is provided by stromatolitic algae from sediments deposited in intertidal or shallow marine environments at least 2,700 m.y. ago¹. It is generally agreed that the earliest metazoan animals were soft-bodied forms which are rarely preserved but have left tracks, trails and burrows, collectively known as trace fossils. The earliest reliably identified trace fossil is a burrow system considered to have been produced by a worm-like organism, probably an annelid, found in shallow marine clastic sediments of the Grand Canyon Series (USA) suggested to be over 1,000 m.y. old². Vertical burrows have been found in the Buckingham Sandstone in North Australia, also a shallow water deposit dated radiometrically as more than 790 m.y. old², and in the Areyonga Formation, of similar age³. A more extensive collection of trace fossils has recently been recorded by Webby⁴ from the clastic shallow marine late Precambrian (about 600 m.y. old) Torrawangee Group of New South Wales (Australia) with three trace fossil genera positively identified: *Planolites*, *Cochlichnus* and *Torrawanga*. The late Precambrian Ediacara Beds of South Australia, also interpreted as shallow water clastic deposits, have yielded one positively identified trace fossil genus (*Cochlichnus*) and five other forms, all thought to have been produced by metazoa². The common factor in these occurrences is the shallow water environment. Most of the trace fossils are burrows of infaunal deposit feeders which inhabited offshore environments of relatively quiet water; but the record of vertical burrows, now most commonly found in the high energy intertidal zone, may indicate occupation of even the shallowest water niches. There is as yet no indication of colonisation of the deep oceans during Precambrian times.

Tracing the dispersal of even soft-bodied benthonic animals from their initial shallow water habitat into deep water is helped by the facies dependence of the trace fossils which they produce. Seilacher⁵ suggested that many trace fossil genera can be assigned to one of three depth-controlled communities and this has, in general, been confirmed by later studies⁶⁻⁸. The communities, each named after a characteristic trace fossil are, in order of increasing water depth: *Cruziana* (littoral to wave base), *Zoophycos* (wave base to

TABLE 1 First appearance of ichnogenera

	<i>Cruziana/Zoophycos</i> community (shallow)	<i>Nereites</i> community (deep)	Ichnogenera independent of depth

zone of turbidite deposition) and *Nereites* (deep water turbidite zone). Thus, by determining the oldest known occurrence of trace fossil genera belonging to the different communities, it should be possible to trace, in time, the dispersal of benthonic faunas into deep water, away from the shallow water niche which they occupied in the Precambrian. Also, by considering the stratigraphical range of the depth-controlled trace fossils, it should be possible to estimate the diversity of trace fossils, and hence animals, in each depth zone at different times. For this analysis, a wide, and as far as possible non-selective, coverage is necessary.

I have therefore considered all ichnogenera (except trace fossils produced by boring organisms) mentioned in a recently published comprehensive text on trace fossils⁹. This text includes papers on all systems and from widespread areas, so that all common traces and some rarer ichnogenera were included but old, inadequately described, ichnogenera were avoided. Each of the depth-dependent ichnogenera was then assigned to its community and its range noted from the *Treatise on Invertebrate Paleontology*¹⁰, modified where necessary to take account of more recent investigations. In all 81 ichnogenera were included.

The results are presented in Tables 1 and 2. Table 1 records only the first appearance of ichnogenera in the stratigraphic column. Table 2 is based on the stratigraphic range of ichnogenera and each ichnogenus is counted as present in every system within its stratigraphic range whether or not it has been recorded from them all.

The tables show a clear trend of increasing diversity in deep water, and possibly decreasing diversity in shallow water, with time. Extension of the survey to include all trace fossil genera in the *Treatise of Invertebrate Paleontology* made no significant difference to the trends but the results are not reported here because of the uncertainty in assigning many neglected and poorly described genera to a community. The diversification seen in the younger Precambrian rocks is continued and markedly accelerated in Lower Cambrian times. Abundant and surprisingly diverse

trace fossils have been recorded from shallow water Lower Cambrian sediments in many parts of the world^{2,11-16} but few forms have been found in deep water deposits. Even simple depth-independent forms are rare in this environment. The contrast between shallow and deep water in the numbers and diversity of trace fossils recorded persists throughout Cambrian times. It cannot be due to any lack of suitable deep water deposits because these are widely distributed and the contrast is clearly seen, for example, in Wales where, despite the great number and variety of traces found in the shallow water sediments, extensive searching in the well exposed deep water turbidite sequences has yielded only a few mostly non-diagnostic burrows¹⁷. Significant colonisation of the deep ocean floor does not therefore seem to have taken place before the close of the Cambrian period.

The widespread shallow water seas of earliest Ordovician (Arenig) times supported an abundant and varied benthos which produced many trace fossils, particularly trilobite traces and infaunal burrows. The first traces assignable to the *Zoophycos* community appeared, including *Zoophycos* itself, which has been recorded low in the Ordovician sequence in Iraq⁵, thus testifying to the colonisation of the intermediate depths. There is also evidence of the first significant colonisation of the deep ocean floor with nine ichnogenera recorded from the *Nereites* community. There is, in addition, an increase in the number of depth-independent ichnogenera from 6 to 13. Data from Upper Palaeozoic and Mesozoic strata suggest the possibility of a further decrease in the number of shallow water forms. The well known abundance of trace fossils in the late Mesozoic and Tertiary flysch successions¹⁸⁻²³ confirms an extensive colonisation of deep water at this late stage, although the very sharp increase in number of ichnogenera present may partly reflect the more detailed study to which these deposits have been subjected. Thus, from the Cambrian to the Tertiary, the available data suggest that the total number of ichnogenera has remained roughly constant, but there has been an increase in the diversity in deep water and possibly a decrease in diversity in shallow water.

The initial colonisation of the deep oceans may have been stimulated by high dispersal pressures in the shallow water niches. Trace fossil abundance and diversity suggest, however, that such pressures reached a high level as early as Lower Cambrian times, yet significant colonisation of the deep oceans was apparently delayed by some 70 m.y., until the Ordovician, when dispersal pressures do not appear to have been much greater. This delay may have been the result of low oxygen concentration in the early deep seas. Most deep water benthos are, however, sediment grazing types; their inability to colonise this environment during the Cambrian may also reflect inadequate supplies of organic detritus within the muds of the early deep ocean floor, together with anaerobic decay brought on by oxygen deficiency in such organic material as may have been present.

No doubt the stratigraphical range of many of the trace fossils used in this analysis will be extended as a result of further work. Nevertheless, the main trends are so clearly shown that it is unlikely that such additions will significantly modify the conclusions which are:

(1) The earliest benthonic metazoa shared a shallow water niche with already existing stromatolitic algae but the algae were restricted to calcareous facies while metazoan trace fossils have so far only been found in clastic sediments.

(2) There was rapid diversification in tracks, trails and burrows in early Cambrian shallow water environments. In contrast, only three genera of deep water trace fossils have so far been recorded from Cambrian sediments and significant colonisation of the deep ocean floor appears to have been delayed by some 70 m.y. until the Ordovician when at least nine ichnogenera were present.

TABLE 2 Number of ichnogenera present during different periods

	<i>Cruziana/Zoophycos</i> community (shallow)	<i>Nereites</i> community (deep)	Ichnogenera independent of depth	Total
Tertiary	12	30	9	51
Cretaceous	18	31	11	60
Jurassic	19	12	13	44
Triassic	19	12	13	44
Permian	18	12	12	42
Carboniferous	22	13	14	49
Devonian	21	12	12	45
Silurian	22	9	12	43
Ordovician	24	9	13	46
Cambrian	24	3	6	33
Precambrian	3	0	1	4

(3) In the late Mesozoic and early Tertiary there appears to have been a sharp increase in abundance and variety of trace fossils produced in deep water but this may partially reflect the more detailed study to which these deposits have been subjected.

I thank R. G. Bromley, R. W. Frey, W. G. Hakes, W. J. Kennedy, A. Radwanski, A. Seilacher and C. Teichert for information allowing me to update the stratigraphical ranges of some of the trace fossils discussed here.

BIOLOGICAL SCIENCES

mRNA is expected to form stable secondary structures

Most sequenced RNAs have the potential to form secondary structures by means of local base pairing and loop formation. Arguments have been advanced that these structures are the result of evolutionary pressure, or of requirements for unique functions such as virus packaging¹⁻⁷. To determine whether secondary structure is an intrinsic or anomalous property of RNA we have investigated random sequences generated by computer. These sequences, which contain no real biological information, can be arranged into thermodynamically stable secondary structures with about 50% base pairing. The results imply that one should expect a high degree of base pairing in RNA, consistent with early estimates of helical content in random copolynucleotides⁸

TABLE 1 Pairing percentages in random structures

Sequence length	No. investigated	% of bases paired
37-62	23	42
77	25	55
144	2	52

and the constraints accompanying structure formation in a hypothetical tRNA molecule^{9,10}. Therefore, the mere existence of secondary structure does not necessarily implicate special biological functions, although the potential for functional interactions clearly exists.

Table 1 shows the average percentage of bases paired in fifty random sequences of various lengths. A sequence was generated by assigning equal *a priori* probabilities to each base and using a standard random number routine to decide which base occupied a particular position along the chain. In each case the computer printed out the base pairing matrix¹¹, facilitating the choice of pairing arrangements by inspection. These arrangements were then evaluated according to rules detailing thermodynamic stability¹¹⁻¹⁵, and the most stable secondary structure was selected in each of the fifty cases. It is possible that occasionally even more stable structures were overlooked; this implies that the resulting base pairing percentages (Table 1) are minimum values. Nevertheless, the most stable structures on the average have 40-60% of bases paired (an example of a random sequence with about 60% pairing is shown in Fig. 1).

Fig. 1 One possible secondary structure for a random sequence of 140 nucleotides. Approximately 60% of the bases are paired.

At fixed length the extent of base pairing observed is not highly variable. Fig. 2 shows the distribution of base pairing in twenty-five random sequences of seventy-seven nucleotides each. Fully 80% of the most stable structures contain 21 ± 3 base pairs, and no structure includes fewer than 15 or more than 28 base pairs. Even though the number of sequences evaluated is small, statistical analysis¹⁶ indicates that these results are applicable to sequences in general with a high level of confidence. The probability that the mean of the distribution shown in Fig. 2 is within $\pm n$ base pairs of the mean of an infinitely large sample is 0.92 for $n =$

1 and 0.99 for $n = 2$. Therefore, the probability of finding a 77-nucleotide RNA, random or real, without secondary structure is very small.

Transfer RNAs (average length of 77 bases) include on average 21 base pairs, but the universality of the resulting clover leaf secondary structure implicates evolutionary selection processes. If tertiary structure and base modifications are ignored, about half the natural sequences can be arranged into structures more stable than the clover leaf. (Many of these retain some elements of the clover leaf, usually the anticodon and acceptor stem. However, the existence of an acceptor stem-like feature in our random structures is an improbable event). The glycyl tRNA from *E. Coli* (Fig. 3) is the most striking example we encountered. It seems possible that selected base modification and specific tertiary interactions prevent these structures from forming under physiological conditions. However, experiments in non-physiological buffers should be interpreted with great care since at low ionic strength extended structures (for example, Fig. 3) may form which minimise the electrostatic free energy.

This structural polymorphism emphasises the need for accurate evaluation of the stability of proposed structures. Optimisation of base pairing is not the only determinant of stability since the size and number of loops is also important. Large internal loops, for example, involve considerable free energy cost and are often overlooked in stability calculations. (Examples include the acceptor stem in tRNA¹⁷ and the flower model 'stalk' in the MS II coat protein gene¹⁸.) When alternative structures are possible that with lowest free energy should be selected. Confirmation is sometimes possible by physical¹⁹ or ribonuclease-digestion techniques¹⁸.

The relationship between the presumably conflicting demands of mRNA secondary structure and amino acid sequence has been the subject of much discussion²⁰⁻²². Our results do not support the hypothesis that amino acid sequences have evolved in part due to pressure for maintaining stable RNA base pairing²². Sequences generated at random exhibit pairing percentages only marginally less than those of the MSII coat protein gene. The distribution of base pairs

Fig. 2 A base pair distribution obtained by randomly generating twenty-five chains, each with seventy-seven base pairs. The height of the shaded area indicates the number of structures which contains the given number of base pairs. The distribution has a mean of 21.3 base pairs and a standard deviation of 2.84.

Fig. 3 A possible secondary structure from *E. coli* glycyl tRNA. The circled bases are modified and do not pair in the clover leaf structure.

in this gene involving degenerate codons²² is consistent with evolutionary pressure on the RNA sequence, or pressure on the protein amino acid sequence, or no pressure at all within statistical uncertainty. Actually, there is no obvious need for RNA to evolve toward structure of minimum free energy. Rather, specific structures should evolve for specific purposes. Defects in pairing which result in instability might even be useful in recognition functions; at the very least they would conserve energy required to disrupt base pairing during translation.

The extent of base pairing exhibited by random structures implies that all mRNAs will form secondary structures. Such high percentages arise naturally from sequences composed of four different types of bases with three allowed pairing possibilities. The absence of secondary structure in mRNA would be surprising and significant. One such example is the polyadenylate sequences present in HnRNA. There is no apparent need to postulate unusual functions or evolutionary pressure on amino acid sequence to explain the existence of stable base pairing in RNA. The results, however, do not imply that there is no evolutionary pressure on RNA sequences, but rather suggest that the existence of such pressure cannot be readily deduced from the observation that a particular messenger has 60% of its bases paired. Finally, it has been suggested that single stranded DNA may be important for control of chromosomal functions²³. Should extensive single stranded regions of average composition exist *in vivo*, they would likely have the potential for formation of stable secondary structure.

We thank Professor Donald M. Crothers for encouragement. This work was supported by a grant to him from the US National Science Foundation.

Hepatoma—foetal Phe-tRNA also present in normal rat liver

SEVERAL groups have demonstrated independently, the presence of two isoaccepting species of Phe-tRNA in rat hepatomas and only one in normal rat liver. By use of reversed phase chromatography on RPC-2 columns¹ two groups²⁻⁴ demonstrated an early eluting, minor peak of Phe-tRNA in Morris hepatomas 5123C and 5123D, which was not seen in normal rat liver tRNA, while one group^{5,6} reported the same extra peak in hepatoma 9618A but not in 3924A. We too have observed this minor peak of Phe-tRNA in Morris hepatomas 5123D, 7777 and 7800 using RPC-2 chromatography. Figure 1a shows a typical RPC-2 pattern for these three hepatomas all of which had a minor Phe-tRNA peak containing 14–15% of the total acid-precipitable counts. Recently Gonano *et al.* reported a similar peak of Phe-tRNA in foetal rat liver which cochromatographs on RPC-2 with the minor peak from hepatoma 5123C⁷.

Recent work in this laboratory, comparing aminoacyl-tRNAs from mouse and rat tumours, has used another reversed phase column system, RPC-5⁸, and fresh isolations of tRNA and aminoacylating enzymes from tumours and normal tissues. The RPC-5 profiles were basically in agreement with those from RPC-2 runs of older preparations and

Fig. 1 a, Elution pattern from an RPC-2 column⁴ on which ³H-Phe-tRNA from Morris hepatoma 7800 (—○—) was cochromatographed with ¹⁴C-Phe-tRNA from normal adult Buffalo rat liver (—●—). b, Elution pattern from an RPC-5 column⁸ on which ³H-Phe-tRNA from normal adult Buffalo rat liver (—○—) was cochromatographed with ¹⁴C-Phe-tRNA from Morris hepatoma 7777 (—●—). Phe-tRNAs were prepared by incubating Sephadex G-100-purified¹³ 4S RNA with aminoacylating enzymes (see below) in a reaction mixture containing 5mM Na₂ATP (neutralised), 100 mM Tris-HCl, pH 7.6, 10 mM MgCl₂, 14 mM β-mercaptoethanol, 0.25 mM each of nineteen amino acids (minus phenylalanine) and 4 × 10⁻⁵–7 × 10⁻⁵ M ³H-L-phenylalanine or ¹⁴C-L-phenylalanine for 30 min at 37° C. The aminoacylating enzymes were prepared from an homogenate of liver or tumour in medium A1 (0.25 M sucrose, 0.006 M MgCl₂, 0.015 M Tris-HCl, pH 7.6, 0.8M KCl and 0.014 M β-mercaptoethanol) from which the cellular membranes and ribosomes had been removed by centrifugation at 100,000g for 2 h. This was absorbed to and eluted from a column of DEAE cellulose by the method of Muench and Berg⁹ and stored in 50% glycerol at -20° C for months (DEAE enzyme), or the S-100 was merely passed over a small column of Sephadex G-10 equilibrated with medium A1 minus sucrose and stored in 50% glycerol at -20° C (G-10 enzyme). After three phenol extracts the labelled Phe-tRNAs were precipitated with ethanol at -20° C, dissolved in column buffer, desalted on Sephadex G-25, mixed and applied to the column specified. The RPC-2 column (1 cm × 240 cm) was eluted at 15° C with a 2 l linear gradient from 0.35 M to 0.65 M NaCl in 0.01 M Na acetate and 0.01 M Mg acetate, pH 4.5. Fractions (10 ml) were collected and precipitated with 1 ml 50% trichloroacetic acid at 4° C, and the precipitates were collected on Millipore filters which were dried, treated with 0.2 ml 1 M KOH for 5 min at room temperature, neutralised with 1 M HCl and counted in a liquid scintillation counter. Three replicate counts were averaged and converted to absolute activity on an IBM 1620 computer. The RPC-5 column (0.5 cm × 50 cm) was eluted at 22° C with a 400 ml linear gradient from 0.5 M to 0.65 M NaCl in 0.01 M Na acetate, 0.01 M Mg acetate and 0.001 M β-mercaptoethanol. Fractions (2.5 ml) were collected, precipitated with 2.5 ml 10% trichloroacetic acid at 4° C, and processed as above.

showed an early eluting peak of Phe-tRNA in hepatomas but not in normal liver (Fig. 1b). While conditions for optimal aminoacylation of phenylalanine to each batch of tRNA were being retested, the DEAE cellulose preparation of aminoacylating enzymes (DEAE enzymes)⁹ from liver or tumour was found not to be as effective in the extent of aminoacylation as was a cruder preparation made by passing a 100,000g supernatant of tissue homogenate over a small column of Sephadex G-10 (G-10 enzymes). The optimal aminoacylating conditions were the same for enzymes prepared by either procedure. RPC-5 chromatography of tRNA from all three hepatomas aminoacylated with G-10 enzymes showed a more prominent early eluting peak of Phe-tRNA (Fig. 1b) than that found by RPC-2 chromatography of tRNA aminoacylated with DEAE enzyme (Fig. 1a). Further, liver tRNA aminoacylated using the G-10 enzyme showed

the presence of a prominent minor peak of Phe-tRNA which had not been seen when the DEAE enzyme preparation was used (Fig. 2).

Because a loss of activity might have occurred during storage of the DEAE enzyme preparation at -20°C in 50% glycerol, a fresh preparation was made from normal rat liver by the procedure used before. Indeed the fresh enzyme was more active in aminoacylating phenylalanine to liver tRNA but not to the extent of a fresh or stored G-10 enzyme preparation. The fresh DEAE enzyme preparation also revealed a very small minor Phe-tRNA peak (Fig. 2), but this was always smaller than the minor peak revealed when the same liver tRNA was aminoacylated with G-10 enzyme.

The G-10 enzyme preparation contained some endogenous tRNA, but the earlier eluting peak of Phe-tRNA was not

Fig. 2 Elution pattern from an RPC-5 column showing the effect of aminoacylating enzymes prepared by two methods on the pattern of Phe-tRNA prepared from normal rat liver. tRNA was aminoacylated with ^3H -L-phenylalanine using liver enzymes freshly eluted from DEAE cellulose (stored at 20°C for less than 7 d) (---○---) and mixed with tRNA from the same source which had been aminoacylated with ^{14}C -L-phenylalanine using liver cytosol merely passed over Sephadex G-10 (—●—) (see Fig. 1 legend for conditions of enzyme preparations and the aminoacylation reaction). The RPC-5 column (0.5 cm \times 30 cm) was developed under high pressure¹⁴ at 22°C with a 150 ml gradient of NaCl from 0.5 M to 0.8 M in 0.01 M Na acetate, 0.01 M Mg acetate and 0.001 β -mercaptoethanol. Fractions (1.2 ml) were collected directly in glass vials and counted in a liquid scintillation counter. Two replicate counts were averaged, and absolute activity was calculated in a PDP-11 computer.

Fig. 3 Four elution patterns from RPC-5 columns using conditions indicated in the legend for Fig. 2. tRNA (30 μg) from normal rat liver (a and b) or Morris hepatoma 5123D (c and d) were aminoacylated with ^3H -L-phenylalanine and chromatographed with 45 μg tRNA from the source that had been aminoacylated with ^{14}C -L-phenylalanine. Reaction conditions are given in the legend for Fig. 1, and the type and source of enzyme used was as follows. a: ---○---, ^3H -Phe, liver RNA, liver DEAE enzyme; —●—, ^{14}C -Phe, liver RNA, 5123 DEAE enzyme. b: ---○---, ^3H -Phe, liver RNA, 5123 G-10 enzyme; —●—, ^{14}C -Phe, liver RNA, liver G-10 enzyme. c: ---○---, ^3H -Phe, 5123 RNA, liver DEAE enzyme; —●—, ^{14}C -Phe, 5123 RNA, 5123 DEAE enzyme. d: ---○---, ^3H -Phe, 5123 RNA, 5123 G-10 enzyme; —●—, ^{14}C -Phe, 5123 RNA, liver G-10 enzyme.

found in it. Mixtures of DEAE and G-10 enzyme preparations yielded Phe-tRNA identical in amount and pattern to that produced by G-10 enzyme only, ruling out the presence of an inhibitor in the DEAE enzyme.

The effect of the two enzyme preparations on tumour tRNA was then studied. Morris hepatoma 5123D and normal rat liver were used as the sources of tRNA and enzymes. Identical amounts of liver tRNA (Fig. 3a and b) and tumour tRNA (Fig. 3, c and d) were aminoacylated with DEAE and G-10 enzymes from liver and tumour in all four combinations and plotted on the same scale. The same type of enzyme preparation, whether from normal or neoplastic tissue, gave the same extent and pattern of aminoacylation of phenylalanine to a particular tRNA preparation. G-10 enzymes increased the total incorporation into the major peak of Phe-tRNA two to three-fold over DEAE enzymes while increasing the incorporation into the minor peak more than fifteen-fold, such that a minor peak not seen in liver tRNA charged with aged DEAE enzyme became very prominent after G-10 enzyme had been used. Furthermore, there

was a distinct difference in the prominence of the minor Phe-tRNA from normal liver and from hepatomas no matter which aminoacylating enzyme was used, but it no longer seems to be accurate to refer to a tumour-specific peak of Phe-tRNA or one completely absent in normal rat liver. In fact, the presence of the minor peak of Phe-tRNA in normal liver has been reported by Tidwell *et al.*¹⁰ in a detailed study of normal and regenerating rat liver.

Possibly a more interesting aspect of these findings is the difference between the two enzyme preparations that enables the minor peak of normal Phe-tRNA to be demonstrated. Work is underway to investigate several possibilities, for example, that DEAE cellulose purification removes or inactivates one of several Phe-tRNA synthetases or a tRNA-modifying enzyme. Tumour tissue may contain such an excess of this factor that the DEAE cellulose step does not remove all its activity.

These investigations have not yet included a study of foetal tRNA, but we suggest that the striking abundance of the early-eluting Phe-tRNA peak in foetal rat liver, reported by Gonano *et al.*⁷, may also be associated with a great abundance of that activity we find deficient in our DEAE enzyme but abundant in the G-10 preparations. The association of neoplasia and foetal gene activation is particularly provocative and this increased amount of a normally minor Phe-tRNA in foetal and neoplastic hepatic tissue should be explored further, remembering that equally significant changes may be occurring simultaneously in the enzymes involved in tRNA aminoacylation. Another product of foetal liver, α -foetoprotein, has also been associated with hepatomas in several species. Apparently α -foetoprotein is secreted by only a limited number of rat hepatomas¹¹, with abnormally high serum levels reported for Morris hepatomas 3924A and 7777 but not for 9618A, 5123D or 7800, all of which (except 3924A⁸) have a prominent peak of the minor Phe-tRNA. Experiments with regenerating rat liver also suggest a transient increase in α -foetoprotein secretion¹², but only normal amounts of the minor Phe-tRNA peak have been reported 12, 18 and 24 h after partial hepatectomy¹⁰. We have not found increases in the minor Phe-tRNA in regenerating liver taken 1, 2, 3, 7, and 10 d after partial hepatectomy. So although both the minor Phe-tRNA and α -foetoprotein may represent increased activation of genes primarily associated with embryogenesis or rapid growth conditions, a direct correlation does not exist between them.

I thank Dr Harold P. Morris for hepatoma lines, Dr F. K. Millar for assistance with computer applications, and Mrs Miranda Dungan for assistance.

Activity of DNA templates during cell division and cell differentiation

THE rates of cellular RNA and DNA synthesis decline during the mitotic stages of cell division¹ and during cell differentiation². The molecular mechanisms mediating such a decline may include changes in the size of mononucleotide pools, changes in RNA and DNA polymerase activity, or changes in DNA template activity³, but previous studies have not distinguished among these possibilities. We have developed a high-resolution electron microscopic technique for directly analysing DNA template activity within living cells⁴, and now report its application to individual cells undergoing division and differentiation in human bone marrow.

Bone marrow spicules⁵ and peripheral blood cells⁶ were isolated under sterile conditions from patients as previously described, and were subjected to the analysis of active DNA templates while in the living state⁴. Acridine orange was used as previously described⁴ to probe for the location and number of active DNA templates within each cell⁵. The location of each probe site was determined by electron microscopic visualisation of the electron-dense reaction product formed between acridine orange and osmic acid⁵. Control experiments omitting either the acridine orange or the DNase steps from the reaction sequence did not reveal any reaction product⁵. Positive cells revealed large (>0.1 μ m) or small (0.025–0.1 μ m) reaction products localised exclusively within the nuclear euchromatin complexes⁵. These probe sites were counted within each cell by one observer, and another observer independently classified the stage of cell division or of cell differentiation, using the ultrastructural criteria previously reported for dividing cells⁷, differentiating granulocytes⁸, and differentiating erythrocytes⁹.

A total of fifty dividing normal bone marrow cells were analysed (Table 1). These analyses revealed a progressive decrease in the number of probe sites per cell through the early and late stages of prophase, to an absence of any probe sites in metaphase, anaphase and early telophase, with a subsequent rapid increase in the number of probe sites per cell in late telophase, returning to a basal level in interphase.

Similarly a total of 123 normal differentiating granulocyte precursor cells and 176 normal differentiating erythrocyte precursor cells (Table 2) were analysed. These analyses revealed a progressive decrease during the course of normal cell differentiation in the percentage of cells containing either large or small probe sites. In addition, these analyses revealed a progressive decrease during cell differentiation in the number of large probe sites per positive cell, as well as a progressive decrease in the fraction of all probe sites represented

TABLE 1. Probe counts in dividing bone marrow cells

Stage of cell division	Mean probe count per cell
Early prophase	35.3
Late prophase	14.8
Metaphase, anaphase, early telophase	0
Late telophase	85.0
Interphase	35.1

TABLE 2 Probe counts within differentiating marrow cells

Granulocytes Stage of cell differentiation	% Cells containing		Mean probe count per positive cell	
	Large probes	Small probes	Large probes	(Large probes)/ (total probes)
Promyelocytes	91.5	100.	9.55	0.19
Myelocytes	85.9	96.4	8.75	0.18
Metamyelocytes	47.6	85.7	3.9	0.05
Band granulocytes	0	20.0	0	0.0
Segmented granulocytes	0	12.2	0	0.0
Erythrocytes Proerythroblasts	100	100	16.0	0.65
Early erythroblasts	84.7	91.6	8.5	0.32
Late erythroblasts	14.8	17.2	3.4	0.20
Nucleated erythrocytes	0	8.3	0	0

by large probe sites (Table 2). These observed decreases in DNA template activity during the course of normal bone marrow cell differentiation are statistically highly significant ($P < 0.01$) by Mann's test for trend significance¹⁰.

Independent analyses have previously revealed a direct correlation between DNA template activity as measured by probe sites within isolated chromatin, and the rate of RNA synthesis by such isolated chromatin when supplied with excess amounts of exogenous RNA polymerase and monoribonucleotides¹¹. The studies reported here measuring probe sites within intact living cells similarly correlate closely with previous independent studies demonstrating a progressive decrease in RNA and DNA synthesis and cell division during normal bone marrow cell differentiation². These quantitative data suggest that a progressive restriction of DNA templates is an important mechanism during normal cell division and bone marrow cell differentiation¹². We are currently studying the molecular species¹³ mediating such restriction and release of DNA template activity during normal⁶ and leukaemic cell division and differentiation¹⁴.

Functional instability of T7 early mRNA

It has been known for some time that mRNA of bacteriophage T7 is stable. Summers¹ measured the decay of acid-insoluble radioactivity in the mRNA after new synthesis was stopped with actinomycin in T7-infected, actinomycin-permeable *Escherichia coli* cells. The half-life of T7 mRNA was estimated greater than 25-30 min at 30° C compared with about 2.5 min for *E. coli* mRNA. Marrs and Yanofsky² showed that the mRNA transcribed from the tryptophan operon is degraded normally in T7-infected *E. coli* but T7 mRNA is stable, measured by hybridisation with T7 DNA. In these experiments only chemical stability of T7 mRNA was studied in terms of acid-insoluble amount or DNA-hybridisable amount and no information was obtained on the functional integrity of the mRNA.

During the late period of T7 infection, only late proteins are synthesised. If T7 early mRNAs are functionally stable and present in the cell together with late mRNA, preferential synthesis of late proteins must depend on some sort of translational control exerted at the level of protein synthesis. However, no discriminatory translational control against early mRNA in T7-infected cells has been detected (submitted for publication). Therefore, we have examined the functional and structural integrity of T7 early mRNA produced by an amber mutant, T7 am193. Since the amber mutation is in gene 1 coding for T7-specific RNA polymerase³, this mutant phage infection on a non-permissive host makes only early mRNA but no late mRNA.

Fig. 1 RNA synthesis in ultraviolet-irradiated D10 F-cells infected with T7 am193. a, ³H-uridine incorporation into RNA; b, T7 DNA-hybridisable ³H-uridine radioactivity in RNA. a, *E. coli* D10 F- was grown in M9 medium at 30° C to a cell density of 6×10^8 ml⁻¹. The culture was chilled and transferred to a glass Petri dish, irradiated for 7 min with two Sylvania germicidal lamps G15TB at 25 cm, then shaken at 30° C for 5 min. Survival was less than 10^5 ml⁻¹. The irradiated culture was then infected with T7 am193 at a multiplicity of 10 and labelled with ³H-uridine (5 μ Ci in 3 μ g ml⁻¹). After 10 min at 30° C, the culture was divided into two. One portion was diluted with an equal volume of pre-warmed medium, the other with pre-warmed medium containing 800 μ g ml⁻¹ rifampicin. Samples of 0.025 ml before dilution and 0.05 ml after dilution were withdrawn and acid-insoluble radioactivity was counted. ●, ³H-uridine incorporation in T7 am193-infected cells; ○, ³H-uridine incorporation in T7 am193-infected cells treated with rifampicin at 10 min (arrow). b, Experimental conditions were the same as described in (a) except that 20 μ Ci in 1 μ g ml⁻¹ of ³H-uridine was added. Samples of 5 ml before and 10 ml after dilution were withdrawn and radioactive RNA was prepared from each. 1.6 μ g of RNA was hybridised to T7 DNA bound to filters¹². A mean value of duplicate samples was plotted. ●, Hybridisable ³H-count in RNA from T7 am193-infected cells; ○, hybridisable ³H-count in RNA from T7 am193-infected cells treated with rifampicin at 10 min (arrow).

Fig. 2 Functional instability of T7 *am193* mRNA in directing *in vitro* protein synthesis. Ultraviolet-irradiated *E. coli* D10 F⁻ was infected with T7 *am193* as described in the Fig. 1 legend. RNA was extracted from the samples withdrawn at indicated times and the messenger activity of the RNA to direct *in vitro* protein synthesis was tested. The cell-free protein-synthesising system contained 5 ²⁶⁰A units of IS₆₀ (pre-incubated cell-free extract) from uninfected D10 cells and 5 μ Ci ³H-phenylalanine in a total volume of 0.25 ml. RNA (40 μ g) from each sample was added as messenger. Incubation was at 35° C for 30 min and hot acid-precipitable radioactivity was counted. ●, Messenger activity of RNA from T7 *am193*-infected cells; ○, messenger activity of RNA from T7 *am193*-infected cells treated with rifampicin at 10 min (arrow).

Our results described here confirmed the chemical stability of T7 early mRNA. We found, however, that functional activity of T7 early mRNA, tested in an *in vitro* protein-synthesising system, decayed at a rather rapid rate, a half-life about 6.5 min at 30° C. We believe that the functional decay is related to a loss of structural integrity of T7 early mRNA without losing much chemical quantity, because acrylamide-agarose gel electrophoresis revealed that the size of T7 early mRNA became smaller parallel to the loss of functional activity.

We used ultraviolet-irradiated bacteria in order to reduce host RNA synthesis after T7 infection. *E. coli* D10 F⁻, derived from D10 by acridine orange treatment (submitted for publication), was irradiated and then infected with T7 *am193*. In ultraviolet-irradiated cells, T7-directed synthesis of macromolecules proceeded somewhat slower than in normal cells. ³H-Uridine incorporation into RNA is shown in Fig. 1a. Ultraviolet-irradiated cells showed an accumulation of T7 early mRNA. Addition of rifampicin effectively shut off new initiation of RNA synthesis but the acid-insoluble radioactivity of the RNA declined only slightly after the addition of rifampicin.

Figure 1b shows the accumulation of T7 early mRNA which can be hybridised to T7 DNA. Ultraviolet-irradiated D10 F⁻ cells were infected with T7 *am193* and labelled with

³H-uridine. RNA was extracted from the cells taken at indicated times. A small amount of RNA synthesised by ultraviolet-irradiated cells without T7 infection did not have any hybridisable radioactivity (not shown in Fig. 1b). Confirming the result of Marrs and Yanofsky², we observed the stability of hybridisable T7 early mRNA even in the presence of rifampicin.

When T7 early mRNA was isolated from ultraviolet-irradiated, T7 *am193*-infected cells and tested for functional activity in an *in vitro* protein-synthesising system, we found that T7 early mRNA lost functional integrity at a rather rapid rate (Figure 2). RNA was extracted from aliquots of the infected culture at various times and added to a protein-synthesising system prepared from uninfected D10 F⁻ cells, and ³H-phenylalanine incorporation was measured. Protein synthesis-directing activity of the RNA decayed at a rapid rate after 15 min of infection even in the absence of rifampicin (Fig. 2). With rifampicin, functional decay of the RNA started earlier. The rate of decay with or without rifampicin was, however, similar.

Figure 3 shows f-met-tRNA binding to ribosomes directed by the RNA taken from ultraviolet-irradiated, T7 *am193*-infected cells. Salt-washed ribosomes and crude initiation factors were prepared from uninfected D10 F⁻ cells. Functional activity of T7 early mRNA in directing f-met-tRNA binding also decayed rapidly (compare with Fig. 3). Decay again started earlier in the presence than in the absence of rifampicin.

Fig. 3 Functional instability of T7 *am193* mRNA in directing the binding of f-met-tRNA to ribosomes. The same RNA samples from the experiment of Fig. 2 were used to direct initiation factor-dependent f-met-tRNA binding to ribosomes. The reaction mixture (submitted for publication) contained 75 μ g of 1 M NH₄Cl-washed ribosomes and 8 μ g unfractionated initiation factors from uninfected D10 F⁻ cells and ³H-f-met-tRNA (1,500 c.p.m. pmol⁻¹) in a total volume of 0.2 ml. RNA (54 μ g) from each sample was added as messenger. Incubation was at 35° C for 15 min and radioactivity of ³H-f-met-tRNA retainable on a Millipore filter was counted. ●, Messenger activity of RNA from T7 *am193*-infected cells; ○, messenger activity of RNA from T7 *am193*-infected cells treated with rifampicin at 10 min (arrow).

FIG. 4 Chemical stability and functional decay of T7 mRNA. Results of Figs 1, 2 and 3, obtained from the ultraviolet-irradiated cells infected with T7 *am193* and treated with rifampicin at 10 min, were replotted. The 100% value represents the value at the time of rifampicin addition (10 min after infection). ●, Acid-insoluble radioactivity in RNA (Fig. 1a); ○, T7 DNA-hybridisable radioactivity in RNA (Fig. 1b); △, messenger activity in RNA to direct protein synthesis (Fig. 2); ▲, messenger activity in RNA to direct f-met-tRNA binding (Fig. 3).

Figure 4 summarises the above results obtained in the presence of rifampicin. After the addition of rifampicin at 10 min of infection, when there was extensive synthesis of phage RNA, there was a slight increase of functional activity due to the residual synthesis of RNA expected from the mode of action of rifampicin. Thereafter, a rapid decay of functional activity in directing total protein synthesis and also initiation factor-dependent f-met-tRNA binding took place. Both decay curves are almost parallel and give an estimate of the functional half-life of T7 early mRNA as about 6.5 min at 30° C. On the other hand, the acid-insoluble and hybridisable amounts of the RNA remained stable.

A loss of structural integrity in T7 early mRNA was found by electrophoresis of the RNA in polyacrylamide gel containing agarose. This method gave a much better resolution for the T7 early mRNA species⁴ than the procedure previously used. RNA extracted from ultraviolet-irradiated D10 F⁻ cells infected with T7 *am193* was labelled with ³H-uridine. Portions of these RNA samples were used for hybridisation experiments (Fig. 1b). Electrophoretic patterns in Figs 5 and 6 show that T7 early mRNAs were partially degraded as time progressed in the absence (Fig. 5) and presence (Fig. 6) of rifampicin. It seems that more smaller size RNAs were produced, at the expense of full size RNAs. Since total radioactivity in the RNA samples taken at different times in the presence of rifampicin was almost the same (see Fig. 1a and b) and relatively large RNAs remained after a long time, it is unlikely that an extensive nucleolytic degradation had taken place. Figure 5 and 6 show that the largest species of T7 early mRNA, gene 1 messenger, over-

lapping with the marker 23S rRNA (see ref. 4) at 10 min (Figs 5a and 6a) shifts to a slightly smaller size as time proceeds (Figs 5 and 6-d).

Our results show that structural integrity and functional activity of T7 early mRNA are closely related. Loss of structural integrity, not detected by measuring chemical amount or hybridisability, plays an important role in messenger function. This warns that hybridisable radioactivity in mRNA is not necessarily a measure of functional activity of the mRNA. Our results also explain why only late proteins are produced in the presence of chemically stable early mRNA in late T7 infection.

Whereas in *E. coli*, mRNAs appear to have identical or similar decay half-lives in functional activity and chemical amount (see ref. 5), a similar difference between hybridisability and functional stability in mRNA was found in single-stranded DNA phage S13 (ref. 6). Messenger RNAs of other phages, ΦX174 (ref. 7) and M13 (ref. 8), were shown to have relatively long half-lives in terms of hybridisability. It would be interesting to know whether these phage mRNAs show a difference between functional and chemical stability.

At the moment we have no direct information as to why T7 early mRNA is chemically stable. Since host mRNA (at least tryptophan mRNA) decays normally in T7-infected cells², T7-directed modification of general mRNA degradation system of the host is unlikely. It is conceivable that T7 mRNA may have structural features, such as extensive base-pairings

FIG. 5 Polyacrylamide-agarose gel electrophoretic pattern of T7 *am193* mRNA. The ³H-labelled RNA samples, used in the hybridisation experiment (Fig. 1b), were analysed by gel electrophoresis. RNA samples (about 1.7×10^5 c.p.m. per sample) were mixed with ¹⁴C-labelled total *E. coli* RNA and subjected to electrophoresis in 2.5% acrylamide-0.5% agarose gel for 1.5 hours at 5 mA per gel^{4,13}. Gels were frozen and sliced into 1 mm pieces. Radioactivity of ³H in each slice was counted⁴. The direction of electrophoresis was from left to right. a, T7 *am193* RNA from ultraviolet-irradiated cells 10 min after infection; b, 15 min; c, 20 min; d, 25 min; —, ³H-labelled T7 *am193* RNA; ---, ¹⁴C-labelled marker *E. coli* RNA, 23S, 16S, and 4S, from left to right.

or special base sequences, such that host mRNA degradation enzyme(s) fail to attack the phage mRNA. An endonucleolytic enzyme, identical or similar to RNase III⁹, is required to process a large single piece of RNA synthesised *in vitro* by *E. coli* RNA polymerase on T7 DNA template. Dunn and Studier¹⁰ showed that this large size RNA, a transcript of entire T7 early genes, can be cleaved to yield several pieces of smaller size RNAs corresponding to the size of *in vivo* T7 early mRNAs. Since RNase III is a double stranded RNA-specific endonuclease, this finding indicates some degree of base pairing in T7 early mRNA.

A preliminary experiment using wild-type T7 phage, instead of T7 *am193*, indicated that the functional activity of both early and late mRNA decays rapidly. Recently, Hagen and Young¹¹ reported that T7 lysozyme mRNA (transcript of one of the large genes) is unstable in directing *in vitro* synthesis of lysozyme.

FIG. 6 Polyacrylamide-agarose gel electrophoretic pattern of T7 *am193* mRNA after rifampicin treatment. RNA samples were as used in the hybridisation experiment shown in Fig. 1b. Electrophoresis was carried out as described in the legend for Fig. 5. a, T7 *am193* RNA from ultraviolet-irradiated cells 12 min after infection (rifampicin was added at 10 min); b, 15 min; c, 20 min; d, 25 min; —, ^3H -labelled T7 *am193* RNA; ---, ^{14}C -labelled marker *E. coli* 23S, 16S, and 4S, from left to right.

This work was supported by a grant from the US Public Health Service. We thank Dr E. G. Minkley for his advice on electrophoresis of T7 mRNA, Drs F. W. Studier and W. C. Summers for stocks of T7 phages and bacteria, and Mr L. Coco for assistance.

Hydrophobic bonding and accessible surface area in proteins

THE hydrophobic bond is the term used by Kauzmann¹ to describe the gain in free energy on the transfer of non-polar residues from an aqueous environment to the interior of proteins. This has been accepted as one of the major forces involved in the folding of proteins. The exact origin of the energy of the hydrophobic bond is controversial², but empirical values have been derived for 10 protein residue side chains by Nozaki and Tanford³ who measured the solubility of amino acids in the organic solvents ethanol and dioxane.

For an atomic group in a protein to interact with the solvent it must be able to form Van der Waals contracts with water molecules. The concept of accessible surface area

has been introduced by Lee and Richards⁴ to describe quantitatively the relationship of proteins to solvent. The accessible surface area of an atomic group is defined as the 'area on the surface of a sphere radius R , on each point of which the centre of a solvent molecule can be placed in contact with the atom without penetrating any other atoms of the molecule'. R is the sum of the Van der Waals radii of the atom and the solvent molecule.

In Fig. 1, the hydrophobicity of each of the 10 protein residue side chains is plotted against its accessible surface area. To derive the hydrophobicity of a side chain Nozaki and Tanford subtracted the value for glycine from that of the amino acid. I calculated the accessible surface areas of protein residue, X , from the accessibilities given by Lee and Richards⁴ for X in tripeptide Ala- X -Ala, where the main chain is in an extended β conformation and the side torsion angles antiplanar. The values for the side chains in Fig. 1 are the accessible surface area of the residue minus the accessible surface area of glycyl (82 Å²).

From Fig. 1 we see that for the non-polar side chains Ala, Val, Leu and Phe there is a linear relationship between hydrophobicity and accessible surface area; the correlation coefficient is 0.998 and the slope equivalent to 22 calorie Å⁻². For the side chains with hydroxyl groups Ser, Thr and Tyr there is a similar linear relationship with a correlation coefficient of 0.998 and a slope equivalent to 26 calorie Å⁻². For residues with similar accessible surface areas those with a polar group are about 1 kilocalorie less hydrophobic than those with only non-polar groups. In aqueous solution the OH, NH, N and S groups will form hydrogen bonds with water. But on transfer to ethanol or dioxane these solute-solvent hydrogen bonds are significantly weakened⁵ and there is therefore a loss of free energy (1-2 kilocalorie per polar group is a reasonable estimate). In proteins this loss does not occur: ~92% of polar groups buried in the interior of proteins form hydrogen bonds. Thus the hydrophobicity of polar side chains will be greater than the values in Fig. 1. A 'correction' of 1-2 kilocalorie per polar group makes the polar residues as hydrophobic as non-polar residues. (The histidine side chain has two polar groups.) This implies that, if hydrogen-bonded, oxygen and nitrogen atoms are hydrophobic; they could, for example, be favourably accommodated in the interior of membranes. This result is related to the finding of Lee and Richards⁴ that when lysozyme, RNase S and myoglobin go from an extended chain to the folded conformation, the reduction in accessible surface area is almost the same for polar and non-polar atoms. Methionine is a little less, and tryptophan a little more, hydrophobic than this argument and the linear relationship illustrated in Fig. 1, would suggest.

In conclusion, we can say that as a good approximation the hydrophobicity of residues in proteins is 24 calorie per Å² of accessible surface area. This value is applicable to protein folding, subunit contacts and the interaction of small molecules with enzymes and immunoglobins. For example the formation of the $\alpha_1\beta_1$ contact in haemoglobin reduces in each monomer the surface area accessible to water by ~900 Å² (my unpublished results). This implies that the hydrophobic contribution to the free energy of dimer formation is 43 kilocalorie. The formation of the contacts that cause the reduction in accessible surface area when proteins fold or aggregate involves large conformational entropy losses^{6,7} and appreciable steric strain (Szabo and Karplus, personal communication) which substantially reduces the figure for the free energy.

The value given here for the hydrophobicity of protein surfaces confirms Kauzmann's hypotheses¹ that the entropic term that stabilises protein aggregation and the binding of small molecules is mainly a result of hydrophobic bonding, and suggests that only relatively small contact areas are necessary for stability. In haemoglobin ~12% of the ac-

Fig. 1 Accessible surface areas of residue side chains (see text) plotted against hydrophobicity (free energy change for the transfer from 100% organic solvent to water³).

cessible surface area of each monomer is covered by the $\alpha_1\beta_1$ contact and $\sim 6\%$ by the $\alpha_1\beta_2$ contact.

In a discussion of the general theory of hydrophobic bonding Hermann⁸ deduced and found a linear relationship between the logarithm of the solubility of hydrocarbons and the surface area of the cavity they form in water. This latter term is equivalent to the accessible surface area of the hydrocarbons.

I thank my colleagues for critical discussion.

Insulin/proinsulin, a new crystalline complex

SINCE the first crystallisation of proinsulin in this laboratory¹, we have tried to grow crystals appropriate for detailed X-ray crystal structure analysis. None of the proinsulin crystal forms prepared proved ideal², and we attempted to cocrystallise insulin and proinsulin. Such crystals, if both components were in ordered array, could provide a basis for the determination of the structure of proinsulin by the use of rigid-body vector search methods^{3,4} using the known stereochemistry of insulin⁵.

Proinsulin is found in crystalline native insulin preparations⁶. It is common to find proteins from inhomogeneous fractions incorporated as impurities into crystals of the

dominant component⁷. Very similar protein molecules, for example, β_1 and β_2 lactoglobulin⁸ often form mixed crystals. These are defect solids, with all crystallographically equivalent positions occupied, but by molecules of different kinds. Steiner⁹ has reported the preparation of what he seems to claim are mixed crystals of insulin and proinsulin of this type. Mixed crystals are not cocrystals if, by this we imply structures with each separate protein ordered by the full symmetry of the space group nor, because of disorder, are they useful for X-ray crystal structure analysis.

We report here the isolation and preliminary X-ray study of a 1:1 crystalline complex of insulin and proinsulin which seems to be a true cocrystalline form.

Cocrystallisation studies were made with both beef and pork hormone/prohormone pairs using the molar ratio 1:1 exclusively. Heterogeneous pairs were not studied. Separate insulin and proinsulin solutions of initial molarities 1.4 mM were prepared by dissolving each protein in 50 μ l of a solution containing 0.05 M sodium citrate, 30 mg ml⁻¹ sodium chloride, and, where used, 0.836 mg ml⁻¹ of zinc chloride and 3 mg ml⁻¹ of *m*-cresol. The final pH was adjusted to 7.25 by addition of 0.5 N HCl. Both proteins crystallise at this pH in the presence of *m*-cresol and zinc; insulin as diamond-shaped plates, proinsulin as tetragonal prisms with pyramidal termination. Hormone and pro-hormone solutions were warmed to 50° C with stirring, then mixed and kept at 50° C for a few minutes. Three vials of bovine material containing cresol and zinc were prepared. All gave a precipitate on cooling to room temperature. Protein-free crystallisation medium was added (with rewarming) to provide a series with final volumes of 130, 150 and 180 μ l respectively. All vials were then kept at room temperature. Small, well-formed crystals began to appear after 2–4 d. The vials were then stored at 2° C. The crystals continued to grow for 1–2 weeks.

All preparations gave crystals. Only tiny, unidentified crystals, 50–60 μ m long grew in the absence of *m*-cresol and/or zinc. The crystals in both pork and beef insulin—

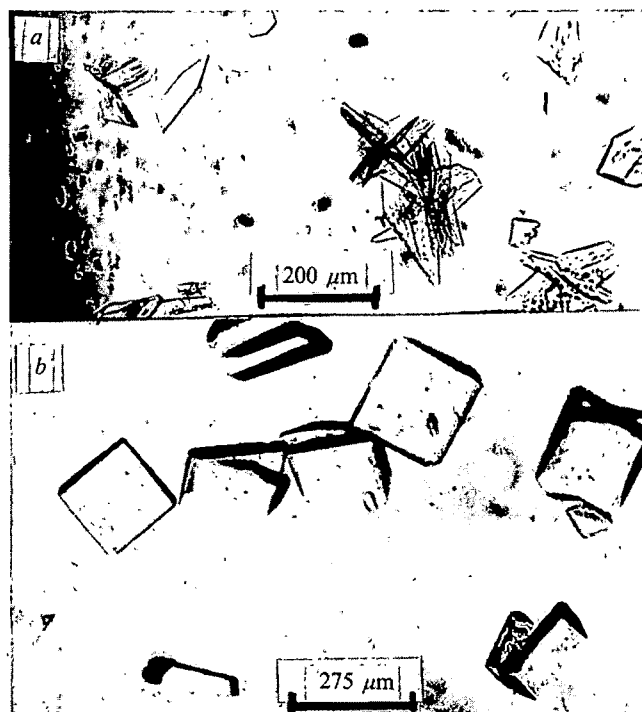

Fig. 1 a, 1:1 crystalline complex of porcine insulin/proinsulin; b, 1:1 crystalline complex of bovine insulin/proinsulin.

Fig. 2 Precession photograph of a bovine insulin/proinsulin complex, 72 h exposure ($\mu = 2.5^\circ$).

proinsulin preparations are clear, colourless plates or wedges which extinguish sharply along the face diagonals under polarised light. The porcine crystals (Fig. 1a) were very thin, and less well formed than the bovine crystals which measured on average $190 \mu\text{m} \times 190 \mu\text{m} \times 30 \mu\text{m}$ (Fig. 1b).

Bovine insulin/proinsulin crystals were mounted in sealed thin-walled quartz capillaries and X-ray precession photographs taken using unfiltered $\text{CuK}\alpha$ ($\lambda = 1.5418 \text{ \AA}$) radiation from a Jarrel-Ash microfocus tube with a pinhole collimator. The crystals turned opaque after less than 30 h exposure to X rays at 20°C (crystals dissolve in their mother liquor at 21°C). Cooling to 15°C retards but does not halt radiation damage.

Useful diffraction patterns were obtained only with the X-ray beam approximately normal to the main face. From still photographs and two small angle ($\mu = 2.5^\circ$) precession films (Fig. 2) the unit cell dimensions were determined to be $257 \text{ \AA} \times 125 \text{ \AA} \times 83 \text{ \AA}$. It was not possible to determine the space group. The two longest dimensions lie along the face diagonals of the crystal.

The unit cell volume is $2.67 \times 10^6 \text{ \AA}^3$. The calculated weight fraction of protein based on a partial specific volume of 0.72 (ref. 1) for both insulin and proinsulin, and a crystal density of 1.20 g cm^{-3} (ref. 1) is 0.52. This is 10^6 daltons, equivalent to twelve hexamers each of insulin and proinsulin per unit cell.

The crystals were analysed by polyacrylamide disc gel electrophoresis, a procedure valid only if the crystals used are identical with the crystals studied by X-ray diffraction. After extensive microscopic survey the larger crystals were removed from those two vials used for X-ray study. These crystals (approximately 100) weighed about $10 \mu\text{g}$. They were washed twice with separate 1 ml portions of protein-free buffer (that is, about 2.4×10^6 times their volume) to remove all non-crystalline protein on their surfaces.

The relative amounts of insulin and proinsulin in the crystals were then determined: The crystals were dissolved in Davis standard buffer (pH 6.7) and applied to gels prepared according to Davis' conditions¹⁰. Similar amounts of insulin and proinsulin were each applied to separate gels as positional standards. Gels were run for 50 min at 8 mA per gel, then stained with Buffalo Black NBR and scanned with a Canaco model E microdensitometer. The gel containing the dissolved crystals showed two bands at the positions of the insulin and proinsulin standards. The relative darkening of the two bands was identical, within 3%, to that on a standard gel run with an equimolar solution of insulin and proinsulin of approximately the same protein concentration.

To verify these findings we wished to use other methods of analysis. Amino acid analysis is insensitive and inappro-

priate because of the close similarity in amino acid composition between the two proteins. An alternative analytical procedure involving separation on a column and subsequent determination of insulin and proinsulin from measurement of absorbance was suggested to us by Steiner (personal communication, 1972) as more reliable than disc gel electrophoresis. It would unfortunately have required the preparation of prohibitively large amounts ($\sim 1 \text{ mg}$) of insulin/proinsulin crystalline material.

We finally chose to calibrate the protein-dye interaction using eleven solutions of insulin/proinsulin with molar ratios varying from 0.5 to 2.0 ($1 \mu\text{g} \mu\text{l}^{-1}$ of protein). The plot of molar ratios of samples against the relative insulin/proinsulin band darkening effects is linear within the range studied and confirms our earlier finding. The insulin/proinsulin ratio is 1:1 within less than 5% maximum error.

We have prepared and characterised a 1:1 crystal complex with approximately twelve hexamers each of insulin and proinsulin per unit cell. As both proteins crystallise separately under the conditions used, there must be strong interactions leading to the new complex between insulin and proinsulin.

The crystals described here differ from any prepared by Steiner. The initial conditions for crystallisation are different (proinsulin has not been crystallised under the conditions used by Steiner). Steiner seems to imply that his crystals are mixed crystals (conforming, at least at low proinsulin ratios, to the dominant rhombohedral insulin form) containing one proinsulin molecule per eleven insulin molecules (8%) that is, on the average one proinsulin per two hexamers, or respectively one, two or three proinsulin molecules per hexamer.

We know of no studies which suggest that insulin and proinsulin form mixed dimers and hexamers in solution. It is difficult to accept the kinetics and equilibria required by the Steiner model—exchanges between homogeneous dimers and hexamers of insulin and proinsulin before crystallisation followed by prompt disassociation and complete reassociation into wholly insulin and proinsulin aggregates in the gel. The precise identity of the Steiner crystals must await adequate characterisation.

We thank Mr Atsushi Sato for his help in the calibration studies of the gel electrophoresis method. This work was supported by grants from the National Science Foundation, NIH and a Public Health Service Fellowship Award to one of us (L. S. R.).

pH-dependent conformational change of gastrin

GASTRIN is a polypeptide hormone with a broad spectrum of biological activities, most notably the stimulation of secretion of gastric acid^{1,2}. It is produced primarily in the pyloric gland area of the lower segment of the stomach, the antrum, which does not secrete acid^{1,2}. When carried by the blood to the upper segment of the stomach, the fundus, gastrin stimulates secretion of acid by the oxyntic glands.¹ Although release of gastrin into the blood stream is mediated by stimuli from the nervous system, its release is strongly inhibited when the antral mucosa is bathed in acid². Therefore, the secretion of the hormone is under negative feedback regulation, with resultant control of stomach acidity.

Human gastrin is a polypeptide composed of seventeen amino acid residues³:

It is found in two forms: without (gastrin I) and with (gastrin II) a sulphate esterified to the hydroxyl group of tyrosine-12. The amino terminus is blocked by the formation of a pyroglutamyl group, and the carboxyl-terminus is blocked as an amide. The carboxyl-terminal tetrapeptide amide fragment (residues 14 to 17) has the full range of physiological activities of the intact hormone⁴. No function for the amino-terminal tridecapeptide (residues 1 to 13) has been demonstrated. A striking structural feature of this portion of the hormone is the sequence of five glutamic acid residues (residues 6 to 10). Synthetic polymers of *L*-glutamic acid have been shown to undergo a transition from random coil to the α -helical conformation as the pH is lowered^{5,6}.

Fig. 1 Circular dichroic spectra of gastrin I at varying pH values. pH: ····, 8.10; —○—, 6.68; ----, 4.85; —, 3.91; —×—, 2.81. Aliquots of a stock solution (1.0 mg ml⁻¹ in 0.05 M NH₄HCO₃) were added to very dilute HCl solutions to give a gastrin concentration of 0.02 mg ml⁻¹ at the indicated pH values. Circular dichroic spectra were measured with a Beckman CD spectrophotometer equipped with a Hewlett-Packard 5480A signal analyser. Measurements of samples in a 1.0 cm path length cell were made at 22°C. All spectra are averages of a minimum of 150 scans. Ellipticities ([θ]) have been expressed in units of degree cm² per decimol of amino acid.

Since the antrum of the stomach is normally bathed in solutions with pH values in this same acidic region, it seemed possible that a similar pH-dependent conformational change of gastrin was involved in the inhibition of its release by acid. As a first step in testing this hypothesis, the circular dichroic spectra of gastrin as a function of pH were studied as probes of its conformations.

The circular dichroic spectra of synthetic human gastrin I (referred to here as gastrin, obtained from ICI, Cheshire,

Fig. 2 Variation of the observed ellipticity of gastrin I at 222 nm with pH. Points were obtained experimentally. The curve is theoretical, and was calculated from equation (1).

England) at varying pH values is presented in Fig. 1. The spectrum measured near neutrality (for example at pH 8.10) has a small positive ellipticity in the 220 to 240 nm range and large negative ellipticity at shorter wavelengths. Qualitatively it is very similar to the spectrum of the random coil forms of poly-*L*-glutamic acid⁷ and poly-*L*-lysine^{7,8}. The circular dichroic spectrum of gastrin in acidic solution (for example at pH 2.81) has two peaks of negative ellipticity at 212 and 220 nm. These negative peaks are in approximately the same positions as the two peaks of negative ellipticity which characterise the α -helical conformations of poly-*L*-glutamic acid⁷ and poly-*L*-lysine^{7,8}. It is interesting that a maximum in negative ellipticity ([θ]) centred near 217 nm which is characteristic of β -structure is absent from all spectra (Fig. 2), indicating the absence of substantial amounts of β -structure. Unfortunately, spectra recorded below 210 nm are not sufficiently free of noise to allow detection of an isosbestic point which would indicate the absence of a conformational intermediate between the random coil and α -helical forms. This low signal-to-noise ratio was a result of the low concentration of gastrin used, which was dictated by its low solubility in acidic solution.

The random coil and β -structure have the same ellipticity at 222 nm⁸. Therefore, the magnitude of observed ellipticity [θ]_{obs} at this wave length (all measurements and values of [θ] used below are at 222 nm) can be used to approximate the helical content of a protein or polypeptide at any given pH. The variation of [θ]_{obs} with pH can be used as a measure of formation and breakdown of α -helical structures with change of pH. A plot of the observed ellipticity at 222 nm as a function of pH is presented in Fig. 2.

As a first approximation in attempting to derive a theoretical treatment to fit the dependence of [θ]_{obs} on pH, two simplifying assumptions have been made. First, the conformational change and resultant change of [θ]_{obs} depends on a single ionisation. Second, only the complete random coil, and the partial α -helical conformations may exist. The points in

Fig. 2 can be fitted to a theoretical curve described by equation (1), where $[\theta]_{\text{obsd}}$ is the

$$[\theta]_{\text{obsd}} = [\theta]_{\alpha \text{ obsd}} \left[\frac{[H^+]}{K_{\text{app}} + [H^+]} \right] + [\theta]_{R+\beta \text{ obsd}} \left[\frac{K_{\text{app}}}{K_{\text{app}} + [H^+]} \right] \quad (1)$$

observed ellipticity; $[\theta]_{\alpha \text{ obsd}}$ is that fraction of the observed ellipticity attributable to α -helical structures, and $[\theta]_{R+\beta \text{ obsd}}$ is that fraction attributable to random coil and β -structures. The terms $[H^+]/(K_{\text{app}} + [H^+])$ and $K_{\text{app}}/(K_{\text{app}} + [H^+])$ define the mol fraction of gastrin in the conformation which predominates under acidic or neutral conditions respectively. The curve shown in Fig. 3 has been calculated to give the best fit to the experimental points with the following values: $K_{\text{app}} = 2.51 \times 10^{-5}$ ($pK_{\text{app}} = 4.6$), $[\theta]_{R+\beta \text{ obsd}} = +300$, and $[\theta]_{\alpha \text{ obsd}} = -8,300$. The apparent pK_a is similar to that for the ionisation of a γ -carboxyl of a glutamic acid residue ($pK_a = 4.4$)⁹. The value of $[\theta]_{R+\beta \text{ obsd}}$ is slightly more positive than $[\theta]_R = -2,780$ and $[\theta]_{\beta} = -2,670$ which have been derived from studies of five globular proteins¹⁰, and within the limits of $[\theta]_R = +3,900$ and $[\theta]_{\beta} = -13,800$ found for poly-L-lysine⁸. Thus, the value of $[\theta]_{R+\beta \text{ obsd}}$ is compatible with gastrin being a random coil in neutral solution. While the theoretical treatment of the pH-dependence of $[\theta]_{\text{obsd}}$ defined by equation (1) gives a good fit to the experimental data, it is probably an oversimplification. Additional factors may be considered which, if included, might give a more precise description of this helix to random coil transition. Their involvement is not obvious in the experimental data, however (Fig. 2).

As a first approximation the fraction of the gastrin molecule which assumes the α -helical conformation in acidic solution can be calculated from equation (2)⁸,

$$\text{fraction } \alpha\text{-helix} = \frac{[\theta]_{\alpha \text{ obsd}} - [\theta]_{R+\beta \text{ obsd}}}{[\theta]_{\alpha} - [\theta]_{R+\beta \text{ obsd}}} \quad (2)$$

where $[\theta]_{\alpha}$ is the ellipticity of a completely helical structure. If a value of $[\theta]_{\alpha} = -35,000$ ⁸ is used, 0.24 of the gastrin molecule, or 4.1 amino acids, assume an α -helical conformation in acidic solution. If the value of $[\theta]_{\alpha} = -31,500$ ¹⁰ is used, 0.27 of the gastrin molecule, or 4.6 residues, participate in the α -helix.

Equation (2) is based on the assumption that ellipticity ($[\theta]_{\alpha}$) is independent of the length of the helix. In fact,

Fig. 3 Ellipticity per decimol of helical segment (that is, $[\theta]_{\alpha} \times$ the number of amino acids per helical segment) plotted as a function of the number of amino acids in the helix. Values of $n \times [\theta]_{\alpha}$ for 5, 10, and 20 residues were calculated from the ellipticities of polymers of alanine^{10,11}; $n \times [\theta]_{\alpha}$ for 11 residues is an average value, calculated from the observed ellipticities of several globular proteins¹¹.

calculated circular dichroism spectra of polymers of alanine¹¹ indicated that $[\theta]_{\alpha}$ decreases with polypeptide chain length, most noticeably for short helical segments^{10,11}. The simplest way to correct for this deviation is by a graphical method. If the ellipticity per decimol of helical segment (that is, $[\theta]_{\alpha} \times n$, where n is the number of amino acids per helical segment) is plotted as a function of the number of amino acids in the helix (n) a linear relationship is obtained (Fig. 3). If only one segment of helix is present in gastrin at low pH, then the ellipticity per decimol of gastrin (that is, $[\theta]_{\alpha \text{ obsd}} \times 17 = 1.41 \times 10^4$) when included in this plot corresponds to $n = 5.2$ residues in an α -helix.

In view of the uncertainty involved in calculating by the above methods the number of residues which assume the helical conformation and the uncertainty inherent in the experimental data, it is reasonable to conclude that the α -helical structure of gastrin contains 5 ± 1 amino acid residues. Since polymers of L-glutamic acid are known to undergo a similar transition from random coil to α -helix, the amino acid residues of gastrin most likely to be involved in α -helix formation are the five sequential glutamic acids (6 to 10).

Gastrins from different species do not always contain the five consecutive glutamate residues. In gastrin from cat, cow and sheep, glutamate 10 is replaced by alanine², and in dog gastrin glutamate 8 is replaced by alanine². Polymers of L-alanine have been studied extensively by X-ray diffraction and found to be in the α -helical form¹². Also, on the basis of energy computations, alanine has been recognised as an amino acid which promotes α -helix formation¹³. Furthermore, in the tertiary structures of seven globular proteins, alanine has been found to have a greater than random probability of participating in an α -helix¹⁴. Thus, the substitution of alanine for glutamic acid in some species is not likely to prevent helix formation, although this has yet to be demonstrated.

Release of gastrin from the pyloric gland area of gastric mucosa of the stomach is inhibited when this tissue is bathed in acid². If gastric acid could interact with gastrin within this tissue, the partial α -helical conformation would be induced. For any of a variety of possible reasons, the conversion of gastrin to the α -helical conformation might prevent its secretion. Thus, the pH-dependent conformational change of gastrin may play a physiological role in the mechanism of acid inhibition of its release.

Stimulation of calcitonin synthesis and release *in vitro* by calcium and dibutyryl cyclic AMP

It has been proposed that the physiological action of calcitonin is to prevent or diminish postprandial hypercalcaemia¹. This is accomplished by inhibition of bone resorption², of the tubular reabsorption of calcium³, and of the intestinal absorption of calcium⁴. Secretion or release of the hormone by parafollicular cells of the thyroid gland is mediated by calcium⁵⁻⁷ and by gastrointestinal hormones including gastrin and pancreozymin^{8,9}. Secretion is apparently influenced by the adenylate cyclase system^{7,10} and hormonal regulation presumably is mediated by cyclic adenosine 3', 5'-monophosphate (cyclic AMP).

We have carried out studies to determine whether calcium and dibutyryl cyclic AMP influence synthesis as well as release of calcitonin. For this purpose slices of porcine thyroid tissue were incubated for 3 h in Krebs-Ringer phosphate buffer. After incubation calcitonin in the incubation medium and in thyroid tissue extracts was determined by radioimmunoassay^{7,11}. As compared with unincubated tissue, there was a three-fold and highly significant mean increase in total calcitonin when tissues were incubated in the presence of a high concentration of calcium, 5.0 meq l⁻¹ (Table 1). Calcium, 7.5 meq l⁻¹, produced mean increases of 75% in the quantity of hormone released into the medium and of 58% in the total amount of hormone as compared to control samples incubated with no calcium in the medium (Table 2). Dibutyryl cyclic AMP, 10 mM, produced mean increases of 28% in the amount of calcitonin released into the medium and of 20% in the total quantity of hormone as compared with control samples incubated with no cyclic nucleotide in the medium (Table 3). These results, which are representative, show that thyroid slices readily synthesise calcitonin during a 3 h period of incubation and that calcium and dibutyryl cyclic AMP produce modest but significant mean increases in calcitonin synthesis as well as secretion.

TABLE 1 Effects of time and calcium* on synthesis and release of calcitonin *in vitro*.

Incubation (h)	Tissue	Calcitonin Medium (ng)	Total	No.

3	461 ± 80	752 ± 66	1213 ± 98	9
	NS		<0.001	

Slices of porcine thyroid glands weighing 100 mg (±5%) were used. Half of them were incubated in 4 ml Krebs-Ringer phosphate buffer, pH 7.4, for 3 h at 37°C under 100% O₂. Slices from a single gland were used in each experiment. Magnesium concentration was 3.1 meq l⁻¹ and glucose concentration was 1 mg ml⁻¹. After incubation, the slices were freeze dried and extracted three times with butanol-acetic acid and water (75:7.5:21)¹². The extracts were combined, freeze dried and taken up in the buffer used for the immunoassay⁷. The unincubated slices were similarly treated. Calcitonin in extracts and medium was estimated by radioimmunoassay in quadruplicate at two different dilutions^{7,11}.

Results are given as ng and are expressed as mean ± one s.e. Student's *t* test was used to determine statistical significance of differences.

* The incubation medium contained 5 meq l⁻¹ of calcium.

Very little is known about the effects of long term stimulation by calcium on either the synthesis or secretion of calcitonin. Gittes *et al.*¹³ showed that calcitonin content in thyroid glands of rats could be reduced by 65% with hypercalcaemia produced by the administration of calcium. Conversely, they demonstrated progressive accumulation of calcitonin content of the thyroid glands with hypocalcaemia produced by parathyroidectomy. Indeed, in the parathyroidectomised animals values of calcitonin content as high as

twelve-fold that of values in control animals were found after 14 weeks. It was concluded that the thyroid gland is much better adapted to secrete calcitonin in response to acute hypercalcaemia than in response to chronic hypercalcaemia.

There is little information currently available concerning the effects and mechanism of action of cyclic AMP to stimulate the synthesis of protein hormones. In pulse-chase experiments, Tanese *et al.*¹⁴ showed that the incorporation of ³H-leucine into insulin and proinsulin and subsequent release

TABLE 3 Effects of dibutyryl cAMP on synthesis and release of calcitonin *in vitro*.

of the hormone and prohormone by isolated islet cells of rats *in vitro* are increased by dibutyryl cyclic AMP. Similarly, Abe and Sherwood¹⁵ demonstrated that incorporation of ¹⁴C-leucine into parathyroid hormone and release by bovine parathyroid tissue *in vitro* is also augmented by dibutyryl cyclic AMP. These studies together with our own suggest that cyclic AMP may modify synthesis as well as secretion of protein hormones.

This investigation was supported by a grant from the US Public Health Service and by research funds from the Veterans Administration. We thank John B. Kimble for technical assistance.

Relationship between measles and canine distemper viruses determined by delayed type hypersensitivity reactions in dogs

MEASLES virus, canine distemper virus and rinderpest virus are classified as members of a subgroup of paramyxoviruses with various interrelationships (reviewed in ref. 1). In some species and in some combinations the viruses may provide a measure of protection against virulent heterologous challenge. This has been the premise for using measles virus vaccine to protect pups against canine distemper at an age when passive maternal immunity often interferes with canine distemper vaccination²⁻⁵.

The principal protection against natural primary measles infection is considered to be cell-mediated immunity^{6,7}, and so it seemed likely that this mechanism also protects against canine distemper. Because of the relationship between the two viruses, we reasoned that measles virus should stimulate the response against distemper. We have tested this hypothesis with dogs to determine whether delayed hypersensitivity reactions could be elicited with both homologous and heterologous antigens.

We used the Edmonston strain of measles virus, which had been through twenty-four passages in human kidney

TABLE 1 Delayed hypersensitivity reaction in dogs sensitised with measles virus after challenge with canine distemper virus

culture, twenty-eight in human amnion culture, six in primary dog kidney culture and two in an established dog kidney cell line (NL-DK-1). The canine distemper virus used was the Snyder Hill strain which had been modified by twenty-eight passages in the NL-DK-1 cell line. The history and tissue culture procedures used for this cell line⁸ and for the viruses⁵ have been described previously. To prepare the sensitising antigens, a large sample of cells growing in Roux bottles was divided into three portions. One portion was infected with measles virus, another with canine distemper virus and the remainder was left uninfected. At the appropriate time, antigens were collected and frozen at -50°C . The live measles viral antigen had a virus titre of $10^{6.26}$ TCID₅₀ ml⁻¹, while that of the live canine distemper viral antigen was $10^{4.63}$ TCID₅₀ ml⁻¹.

Cells used to prepare the skin test reagents were handled similarly except that after collection the virus was concentrated by differential centrifugation. Fluids were centrifuged at 2,000 r.p.m. in a 267A head in a model BE International centrifuge for 15 min followed by centrifugation at 55,000 r.p.m. in a SW 27 head on a model L3 Beckman centrifuge at 5°C for 120 min. After resuspension of the pellet in Hanks balanced salt solution, virus had been concentrated about forty-fold. The cell control antigen was handled in an identical manner. The resuspended concentrates were then treated with Tween-80 and ether as described by Norrby⁹ which served to inactivate the viral antigens.

Our test procedure determined by preliminary experiments consisted of a single inoculation with a sensitising antigen (live virus) followed 10-30 d later by test inoculations with skin test reagents. The sensitising inoculations of 5.0 ml were given intramuscularly in the hind legs. Test inoculations of 0.2 ml were given subcutaneously in the inside surface of the ears. Up to three different antigens were inoculated at separate sites in each ear with inoculations being repeated bilaterally. Dogs had to be kept at a minimum temperature of 20°C , as at a lower temperature cold ears interfered with the test and gave false negative reactions. (This is important if experiments are conducted with animals maintained in the open.) Immediately before each inoculation, blood samples were tested for neutralising antibodies against both canine distemper and measles viruses⁵. Samples collected at the first inoculation were tested to determine that dogs had not been exposed previously. Samples collected at the second inoculation were tested to ensure that each dog had shown an appropriate response to the sensitising antigen alone. Dogs were examined 4, 24, 48, 72 and 96 h after subcutaneous challenge. No reactions indicative of an immediate hypersensitivity response were observed at 4 h. The first positive reactions, palpable at 24 h, consisted of a small region characterised by oedema and induration which had generally increased in size at 48 h. Lesions were not characterised by erythema. At 72 and 96 h the lesions were smaller but still palpable and gradually disappeared in about a week. In some experiments, dogs were rechallenged and the lesions tended to be larger and occasionally exhibited central necrosis.

Fig. 1 Delayed hypersensitivity reaction in ear of dog sensitised with measles virus. Perivascular infiltration of small lymphocytes and some polymorphonuclear leukocytes was seen 24 h after challenge with canine distemper viral antigen prepared as previously indicated. Haematoxylin and eosin stain, magnification $\times 224$.

TABLE 2 Delayed hypersensitivity reactions in dogs

Sensitising antigen	Challenge antigen		
	Canine distemper	Measles	NL-DK-1

Measles	3/3	3/3	0/3
NL-DK-1 (control)	0/2	0/2	0/2

* Numerator indicates number of positive reaction sites, denominator indicates number of dogs tested.

The purpose in our first experiment was to determine by comparison of lesions and histological sections whether sensitisation with measles virus would cause a dog to respond to a challenge with canine distemper antigen with a typical delayed hypersensitivity response (Table 1). Dogs sensitised with canine distemper virus or NL-DK-1 cells served as controls. Fourteen days later dogs were inoculated bilaterally with both canine distemper antigen and the NL-DK-1 cell antigen as control. After 24 h, under general anaesthesia, punch biopsies approximately 20 mm in diameter were removed at the sites of inoculation from one ear. After 48 h, similar biopsies were made on the other ear. Tissues were fixed in 10% neutralised formalin and stained with haematoxylin and eosin. The cell types seen in the lesions after 24 h were a mixture of mononuclear cells and polymorphonuclear leukocytes (Fig. 1). By 48 h the former were predominant. This response is similar to that reported for other antigens that induce delayed type hypersensitivity reactions in the dog¹⁰.

In the second series of experiments, we extended the observations of delayed hypersensitivity responses to both homologous and heterologous antigens. One month after the first inoculation, test inoculations were made bilaterally on each ear with all three antigens. Table 2 shows that animals sensitised with canine distemper virus exhibited delayed hypersensitivity reactions when challenged with canine distemper or measles antigen. Animals sensitised with measles virus and challenged with both antigens also exhibited delayed hypersensitivity reactions. Sensitisation and challenge with preparations of NL-DK-1, which were uniformly negative, served as controls to assure that the reactions seen were not a result of response to components of the culture system. It is possible that common envelope antigens acquired from the membrane of the NL-DK-1 cells could be involved in cross reactions. This would be true if the acquired antigens were masked or inactive on the NL-DK-1 cells but were exposed and active when incorporated in the viral envelope.

So far no underlying immunological mechanism has been identified for heterotypic immunity, which is the veterinary term for the concept of using one virus to provide protection against another. This demonstration of delayed hypersensitivity to measles and canine distemper virus, and of cross reactions suggest that cell-mediated immune response is the mechanism by which measles vaccine protects pups against canine distemper virus.

We thank Dr Richard B. Wilson for consultation in pathology.

Natural resistance to *Salmonella* infection, delayed hypersensitivity and Ir genes in different strains of mice

THE development of immunity to an intracellular bacterial infection such as that produced by *Salmonella typhimurium* in mice can be followed by the fall in the numbers of living bacteria in the liver and spleen. Resistance to infection appears at about the same time as delayed hypersensitivity to appropriate antigens of the infecting organisms and both may be taken as indicators of a cell-mediated immune response¹. Inbred mouse strains differ widely in their resistance to salmonella infections and one possible explanation is that they differ in their ability to produce cell-mediated immune responses in general. This has been tested by comparing the degrees of delayed hypersensitivity detectable in different strains of mice sensitised with a number of unrelated antigens. The results discussed here disprove the hypothesis but suggest a more interesting one.

Six strains of inbred mice of differing ancestry² were taken and the LD₅₀ for each, calculated after subcutaneous infection with *S. typhimurium* C5 (Fig. 1). The mouse strains could easily be separated into those sensitive to less than 100 organisms and those resistant to over 10⁵. No intermediate grades of resistance were found.

An extract was prepared from a 48 h culture of *S. typhimurium* by an adaptation of the method of Collins and Mackaness³ and the final protein concentration adjusted to 1 mg ml⁻¹. Mice infected with *S. typhimurium* 8 d previously were challenged by the injection of 0.025 ml of extract into the right hind footpad. The left hind footpad was injected with phosphate-buffered saline, and similar injections were made in unsensitised mice. Other mice of each strain were sensitised with BCG, picryl chloride and oxazolone. Mice

were sensitised to BCG by intravenous injection of 10^5 live organisms and challenged 5 weeks later with 0.025 ml of tuberculin purified protein derivative (PPD) ($10 \mu\text{g ml}^{-1}$). Picryl chloride and oxazolone were applied to the clipped backs of the mice as 0.1 ml of a 3% solution in alcohol. Mice were challenged after 7 d with 2 drops of a 1% solution in olive oil spread on the right ear lobe, using pure olive oil as a control on the left.

Increases in thickness of footpads and ears were measured by a micrometer 4, 24 and 48 h after challenge. The immediate reaction subsided at 6 h and was followed by an increased reaction reaching a maximum at 24–48 h. This was accompanied by a mononuclear cell infiltration into the area, typical of a delayed hypersensitivity reaction. All the results have been corrected for the increases found in sensitised and unsensitised controls.

In the first series of experiments the sensitive strains were sensitised with ten *S. typhimurium* organisms and the resistant with 10^3 . Although the resistant strains clearly developed an increased delayed hypersensitivity reaction to the extract, this could conceivably have been a result of the larger sensitising dose they had been given. All the mouse strains were therefore sensitised with a low dose of *S. typhimurium*. The resistant strains still gave a significantly greater reaction, which was confirmed by a similar experiment in which all strains of mice were given a high sensitising dose of the avirulent strain of *S. typhimurium*, M525, (Fig. 2a). In contrast, the responses to BCG, picryl chloride and oxazolone (Fig. 2b) were similar in all strains of mice (Table 1). Strains of mice naturally resistant to *S. typhimurium* infection therefore show a greater capacity than sensitive strains to develop delayed hypersensitivity reactions to *S. typhimurium*. This is, however, a specific reaction to a salmonella antigen or antigens and not a general capacity to develop good cell-mediated immunity. This finding is in agreement with that of Robson and Vas³, who were able to immunise their resistant more readily than their susceptible mouse strains, using a variety of salmonella antigens. They suggested that the immunity produced was cell mediated and pointed out that the response to other organisms such as *Listeria monocytogens* and *Cryptococcus neoformans* did not run parallel.

The differences in resistance to salmonella infection of the inbred strains of mice must clearly have a genetic basis. The polarisation into strains of high and of low resistance with the absence of intermediate strains suggests that only a small number of genes, or even only one, is involved. Here our results differ from those of Robson and Vas who found that C3H/HeJ strains were susceptible and DBA/2J were intermediate. Both they and we used *S. typhimurium* C5 (obtained from Professor Rowley) as the challenge organism. The difference in results may well be due to the different routes of infection used, intraperitoneal by Robson and Vas, subcutaneous in our present work. Mice infected intraperitoneally are frequently more susceptible than when infected by the subcutaneous or intravenous routes. In the

poorly protected peritoneal cavity, bacteria have a chance to grow up; effectively increasing the inoculum^{4,5}. This is supported by the relatively low doses of bacteria which killed A/J mice in Robson and Vas's experiments compared with ours. Precise comparison of results is made difficult because we have expressed resistance in terms of LD₅₀ whereas Robson and Vas have measured prolongation of survival time.

Comparison of the results presented here with those of Levine⁶ and of Vaz *et al.*⁷ shows that the resistant strains A, CBA and C3H are those which readily produced antibodies to low doses of a benzylpenicilloyl-bovine gamma globulin complex (BPO-BGG) or of ovomucoid but gave little or no response to ovalbumin. In contrast the susceptible strains C57Bl, Balb/c and B10-D2 responded poorly to BPO-BGG and ovomucoid but well to ovalbumin. DBA/2 mice which were the least resistant of the resistant group are anomalous in that although they responded to the salmonella extract they did not respond to BPO-BGG or to ovomucoid and relatively poorly to ovalbumin. Moreover, when sensitised with large

FIG. 2 a, Delayed hypersensitivity reactions to salmonella extract in mouse strains sensitised with 10^4 *S. typhimurium* strain M525. b, Delayed hypersensitivity to oxazolone. Increased thicknesses in mm of footpads (a) and ears (b) are the corrected means of the 24 h and 48 h values.

doses of the avirulent strain of *S. typhimurium* M525 they invariably died within 4 h of being challenged with the salmonella extract, apparently with some acute hypersensitivity reaction. Delayed hypersensitivity could not therefore be measured in these experiments.

Production of antibody to ovomucoid, ovalbumin and BPO-BGG in mice is thought to be controlled by immune response (Ir) genes⁶⁻⁹ and these are closely, though perhaps not invariably, associated with histocompatibility genes. In the data so far, the resistant strains A/J are H2a, CBA and C3H are H2k, of the susceptible strains, C57Bl are H2b and Balb/c H2d. DBA/2 is again odd in being resistant, but H2d. Ir genes are generally dominant. Preliminary experiments with the F₁ generation of a Balb/c, CBA cross show that resistance is also dominant. Further experiments with backcrosses to check the relations between resistance and antibody responses to ovomucoid and ovalbumin and H2 types are in progress. At present, we suggest that a major factor in the resistance of mice to salmonella is the presence of an Ir gene controlling the response to some unknown but probably protein antigen present in *S. typhimurium*. Further characterisation of this antigen is required. In the extensive literature^{10,11} on the basis of genetic resistance to salmonella infections in mice, many effector mechanisms such as antibody production, cellular immunity, phagocytic activity and macrophage bactericidal capacity have been considered. Current work on Ir genes using synthetic and other antigens may help solve the problems.

Specific degranulation of human polymorphonuclear leukocytes

THE human polymorphonuclear leukocyte (PMN) contains two types of cytoplasmic granules, specific or heterophil granules and azurophil granules¹. These granules contain enzymes and various non-enzymatic proteins. The specific granule contains alkaline phosphatase and most of the lysozyme of the cell while the azurophil granule contains the acid hydrolases and other enzymes which identify it as a lysosome¹. Recent work² has shown that in the degranulation accompanying phagocytosis the specific or heterophil granules combine with the phagosome first, followed by the azurophil granules. This implies that degranulation may be a complex event with more than one signal involved. If this were true

then one might expect that the events should be separable, that is, that one type of granule might be stimulated and the other little affected. Experiments in our laboratories have indicated that only one type of PMN granule responds to phorbol myristate acetate (PMA). Five minutes after application of nanogram quantities of the agent the cell begins to show large intracellular vacuoles. Granules which demonstrate an alkaline phosphatase reaction disappear in 30 min while those staining for myeloperoxidase remain³. Here we report that PMA causes both a dose and a time dependent release of enzyme activity associated with specific granules while those associated with azurophil granules or lysosomes remain associated with the cell as did a cytoplasmic marker enzyme glucose-6-phosphate dehydrogenase.

Fig. 1 a, Lysozyme; b, myeloperoxidase; c, β -glucuronidase. PMN (3×10^7) were incubated with or without PMA added at 0 time. The percentage of total enzyme released into the HBSS solution is indicated and in each case a time-matched control without PMA was subtracted from the total enzyme released. o, 5 ng ml⁻¹ PMA; •, 20 ng ml⁻¹ PMA.

The human PMN used in these studies were all sedimented through dextran and washed as previously described⁴. Red blood cells were lysed by 0.87% ammonium chloride⁵. The cells in these preparations were approximately 85% PMN, the remainder comprising lymphocytes, monocytes and platelets. These cells were incubated in a CO₂ incubator in Hanks Balanced Salt Solution (HBSS) without phenol red or serum. At the end of each incubation the cells were sedimented at 250 g and the supernatant was used for determination of enzyme activity released from the cells. The cell pellet was resuspended in 0.2 M sucrose plus 0.1% Triton X100 and then quick frozen (acetone-dry ice) and thawed five times. The enzyme activity in this material was defined as cell associated. Addition of this activity and that released from the cells is defined as total enzyme activity. The pH of the supernatant was not altered by the addition of PMA. The addition of the supernatant to the enzyme reaction mixtures described below did not alter the pH of these mixtures. The procedures for assay of lysozyme, myeloperoxidase, glucose-6-phosphate dehydrogenase⁶, β -glucuronidase⁷ and alkaline phosphatase⁸ are described elsewhere. In each experiment, illustrated in Table 1 and Fig. 1, assay of cell-associated enzymes in the presence and in the absence of PMA indicated that PMA did not inhibit or enhance the activity of any of the enzymes tested. The cells were not permeable to trypan blue either at the start or end of each experiment. In addition, the cells did not lyse during the incubation, since they fail to release either the cytoplasmic enzyme (glucose-6-phosphate dehydrogenase; not shown) or enzymes of the azurophil granule.

TABLE 1 Effect of PMA on the release of enzymes from polymorphonuclear leukocytes

	Incubation time (min)	Lysozyme	Percentage of total enzyme released* Alkaline phosphatase	Glucuronidase
Control	15	4.7	—	7.1
5 ng ml ⁻¹ PMA	15	21.4	29.5	6.4
20 ng ml ⁻¹ PMA	15	31.5	41.0	5.7
20 ng ml ⁻¹ PMA	5	7.3	10.4	3.2

* Calculated from loss of cell-associated enzyme during incubation of PMN with PMA, compared with cell-associated enzyme at 0 time and cell-associated enzyme of matched control incubated in the absence of PMA. The presence of phosphate buffer in the medium (HBSS) precludes the determination of alkaline phosphatase activity in the medium. Alkaline phosphatase activity released in this table therefore represents the difference between total enzyme activity of control and experimental values.

PMA was obtained from Consolidated Midland Corp. Brewster New York. Each lot was examined by a mass spectrometer (showed a single molecular weight of 616) and by thin layer chromatography (migrated as a single spot).

Table 1 and Fig. 1 illustrate the effects of PMA on the release of enzyme from the PMN. Table 1 shows that both lysozyme and alkaline phosphatase responded similarly to comparable concentrations of PMA. In this experiment the amount of β -glucuronidase released was similar in control cells and cells exposed to PMA. Figure 1 shows the time course of release of lysozyme, myeloperoxidase and β -glucuronidase after treatment with 5 and 20 ng ml⁻¹ PMA. In this experiment all enzyme activity shows an increase which is dependent on both PMA concentration and time of exposure. However the enzymatic activity represented in the specific granule (lysozyme) rises sharply and early. The lines in the graph are not carried through the origin since little or no release of enzyme activity is detectable in the 5 min after addition of PMA (see Table 1). In all of these experiments the cytoplasmic enzyme glucose-6-phosphate dehydrogenase did not appear in the external media.

Our data indicate that PMA causes the external degranulation of the PMN specific granule. Enzyme activity associated with this organelle is either present in the media and (or) lost from the cells after exposure to PMA. This event depends both on dose and time. Enzyme activities associated with azurophil granules remain almost entirely associated with the cell. These findings are consistent with observations that the alkaline phosphatase reaction is absent in cells exposed to PMA while large myeloperoxidase-negative vacuoles arise within the cells³. In addition myeloperoxidase-staining organelles continue to be present in cells containing many vacuoles³. This is the first report of external degranulation of specific granules alone. One of the early effects of PMA is to cause a rapid rise in intracellular cyclic GMP concentration in both 3T3 fibroblasts and human platelets⁹. Further, our previous experiments¹⁰ have implicated cyclic GMP as the intracellular mediator of the action of PMA on the PMN to enhance chemotaxis. Other workers have also indicated that external degranulation of PMN which involves both specific and azurophil granules¹¹ may be enhanced by agents which increase intracellular cyclic GMP and by cyclic GMP itself^{12,13}. This suggests that PMA causes external degranulation by a mechanism which may be initiated or modulated by an increase in cyclic GMP concentration. As Bainton² has demonstrated, however, internal degranulation involves both types of granular organelles in sequence; first the specific granule and then the azurophil granule rapidly fuse with the phagosome. A similar sequential mechanism probably also operates in external degranulation. If this is the case, then exposure to PMA results in the initial half of the event, fusion of the specific granule with the external cell membrane. Subsequent events leading to fusion of azurophil granules with the membrane do not occur. Our observations, then, combined with those of Bainton² suggest that two signals may exist for degranulation.

Calcium does not uncouple oxidative phosphorylation in tightly-coupled mitochondria from Ehrlich ascites tumour cells

ENERGY-linked Ca²⁺ accumulation occurs in mitochondria isolated from different tissues and species (for reviews, see refs. 1 and 2). If the Ca²⁺ concentrations are kept relatively low, such accumulation does not lead to any apparent biochemical damage to the mitochondria, particularly to those processes associated with ATP synthesis. Once the concentration of Ca²⁺ in the incubation system approaches values of 100–150 nmol per mg protein, however, the ion induces mitochondrial swelling, release of the accumulated Ca²⁺ and total loss of acceptor control of respiration^{3–6}. The latter situation is brought about through an increase in state IV respiration to a rate which approaches that of state III.

Other events which occur include stimulation of ATPase activity, greatly diminished ADP-ATP exchange and ^{32}P -ATP exchange activities and P/O ratios^{4,6}. All these events reach maximum at approximately identical concentrations of Ca^{2+} and so seem to reflect some common interaction of this ion at the intact (inner) membrane with which these energy-linked reactions are intimately associated.

On studying the interaction of Ca^{2+} with tightly coupled mitochondria isolated from Ehrlich ascites tumour cells (refs 7, 8 and R. F. W. T. and F. L. B., submitted for publication) these organelles showed membrane-linked responses to Ca^{2+} quite uncharacteristic of those seen in mitochondria isolated from most normal mammalian tissues, for example rat liver. The most conspicuous uncharacteristic response in these tumour mitochondria was the inability of Ca^{2+} to uncouple phosphorylation from respiration. The mitochondria are highly tolerant to exceptionally high concentrations of Ca^{2+} . Consequently, membrane-bound, energy-linked reactions normally grossly modified in the presence of 100–150 nmol Ca^{2+} per mg protein are either insensitive to or only slightly modified by concentrations as high as 300 nmol per mg protein. This finding suggests an altered metabolic behaviour in some tumour cells.

Mitochondria were isolated from a hyperdiploid strain of Ehrlich ascites tumour cells, by methods described elsewhere^{7,8}. EDTA was present in the original isolation medium but was omitted from the medium used for the final washings of the mitochondria. The acceptor control of respiration and oxidative phosphorylation were both measured as described in the legends accompanying the appropriate figures. Oxygen uptake was measured using an oxygen electrode coupled to a Rikadenki pen recorder.

ADP-ATP and ^{32}P -ATP exchange activities were measured as previously described⁹, with the exception that in the case of the ADP-ATP exchange reaction the adenine nucleotides were separated by DEAE-cellulose paper chromatography¹⁰. ATPase activity was monitored by measuring the appearance of P_i in the medium using the method of Baginski *et al.*¹¹

Sonication of the mitochondria was carried out using six 15-s intermittent exposures on an MSE 100 W sonicator, using a small probe. The suspension of mitochondria was maintained on ice during this period. The acceptor control ratio after sonication was one.

Ca^{2+} accumulation by mitochondria was measured using $^{45}\text{Ca}^{2+}$; Millipore filters (pore size 0.45 μm) were used to separate the mitochondria from the suspending medium.

The reagents used were all of AR grade. Adenine nucleotides were obtained from C. F. Boehringer and Sonne, Mannheim, Germany. Radioactive $^{45}\text{Ca}^{2+}$ was obtained from the Radiochemical Centre, Amersham, England. ^{32}P was obtained from Lucas Heights, New South Wales, Australia.

The traces shown in the inset to Fig. 1 illustrate the influence of high calcium concentration on the rate of respiration before (state IV) and after (state III) addition of ADP. Trace *a* indicates that ADP stimulated respiration some 3.5-fold in the absence of added Ca^{2+} . The amount of ADP added was such that state III respiration proceeded to anaerobiosis.

Trace *b* was obtained with an identical incubation medium except that Ca^{2+} (660 nmol) was added to the system before the addition of mitochondria. With the particular sequence of additions made in these experiments (Ca^{2+} before mitochondria) it is not possible to measure quantitatively the amount of extra oxygen taken up by the mitochondria due to the Ca^{2+} present in the medium. The rate of oxygen uptake was, however, qualitatively greater for a short period immediately following the addition of mitochondria; this increased rate would reflect the stimulation by Ca^{2+} of state IV respiration in these mitochondria as reported elsewhere (ref. 7, and submitted for publication). A most unusual feature of the trace is that despite accumulation and retention of this large

amount of Ca^{2+} by the mitochondria (submitted for publication) (and see below), the rate of respiration after accumulation was complete and did not increase significantly as it does with rat liver mitochondria^{1,4,7}. Also addition of ADP had no effect on the rate of respiration. These experiments are described in more detail elsewhere (submitted for publication).

The remaining data in Fig. 1 were obtained from traces similar to those described above but over a wide range of Ca^{2+} concentrations. The ADP-stimulated rate of respiration gradually declines to approach the same as that in the absence of ADP at about 250 nmol per mg protein. The acceptor control ratio which is maximal in the absence of added Ca^{2+} also gradually declines to a value approaching 1 at the same high level of Ca^{2+} .

Three features of these data thus contrast with the events that are seen under identical experimental conditions with mammalian mitochondria such as those isolated from rat liver (compare with data from ref. 4): (a) the ability to accumulate and retain high levels of Ca^{2+} , (b) the complete lack of an increase in the resting rate of state IV respiration once the high levels of Ca^{2+} have been accumulated by the mitochondria and (c) the inhibition of succinate-supported state III respiration.

Although the acceptor control ratios obtained with both rat liver and the ascites tumour mitochondria each approach a value of unity as the concentration of Ca^{2+} in the medium is increased (contrast data in ref. 4), it is important to note that each does so for entirely different reasons. With the liver mitochondria the value approaches unity because the rate of state IV respiration increases to that of state III.

Fig. 1 Influence of Ca^{2+} concentrations on states III and IV of respiration in intact mitochondria isolated from Ehrlich ascites tumour cells. The incubation system contained (in order of addition) 80 mM sucrose, 16 mM Tris-HCl (pH 7.4), 1 mM (K) phosphate, 7 mM succinate, increasing concentrations of Ca^{2+} (containing $^{45}\text{Ca}^{2+}$) as indicated and 2.2 mg of mitochondrial protein. The total volume was 1.5 ml and the reaction temperature 25° C. Oxygen uptake in state IV (○) was measured for approximately 2 min before the addition of 1 mM ADP. When the state III trace (●) approached anaerobiosis (usually approximately 4 min after addition of ADP) a sample of medium was removed and filtered (Millipore; pore size, 0.45 μm) and the mitochondria analysed for the presence of $^{45}\text{Ca}^{2+}$ (▲). Numbers in brackets in the inset are the rates of O_2 uptake in the absence (a) and presence (b) of 660 nmol Ca^{2+} .

Fig. 2 Influence of Ca^{2+} concentration on the P/O ratio in intact mitochondria from Ehrlich ascites tumour cells. The incubation system was identical to that described in Fig. 1 except that $^{45}\text{Ca}^{2+}$ was not added. Also, phosphate (containing approximately 0.5×10^6 c.p.m. $^{32}\text{P}_i$) was added with the ADP. An aliquot of the reaction medium was removed into perchloric acid for assay of esterified $^{32}\text{P}_i$ at a known time, approximately 3 min, after addition of the ADP plus $^{32}\text{P}_i$. The P/O ratios were calculated from the total oxygen uptake from the time of the combined addition of ADP and $^{32}\text{P}_i$ until the reaction was stopped in perchloric acid.

With the tumour mitochondria, however, state III respiration declines to approach that of state IV.

The unusual respiratory behaviour of the tumour mitochondria induced by Ca^{2+} as described above prompted an examination of the effect of this ion on the P/O ratio. Data from one such experiment are shown in Fig. 2. The curve relating phosphate esterification to Ca^{2+} concentration shows only a gradual decline over the entire range of Ca^{2+} concentrations examined. At no stage is there any sign of the marked response of this function to Ca^{2+} as seen for example in rat liver mitochondria⁴. A most unusual and potentially significant consequence of the data is that since both state III respiration and phosphate esterification decline to similar extents there is little significant change in the P/O ratio. Thus at a Ca^{2+} concentration of 300 nmol per mg protein, the P/O ratio for succinate is still only about half of that observed in the absence of Ca^{2+} .

Since the partial reactions mentioned in the first few paragraphs reflect aspects of the mechanisms of oxidative phosphorylation, we examined the effect of Ca^{2+} on these reactions. Figure 3 shows the influence of Ca^{2+} on the $^{32}\text{P}_i$ -ATP exchange activity in intact and sonic ascites mitochondria. Since the data in the literature for the rat liver system is inadequate for the present purposes, experiments carried out with mitochondria from this tissue have also been presented. The gradual decline in activity in the ascites mitochondria is again clearly evident and contrasts with the sharp response seen with rat liver mitochondria at about 100 nmol per mg protein. The response to Ca^{2+} of this exchange in intact ascites mitochondria is almost identical to that observed with sonic preparations suggesting that Ca^{2+} does not interact with the intact ascites mitochondria in the same way as it does with the intact rat liver mitochondria.

The response of the ATPase and ADP-ATP exchange activities to Ca^{2+} in intact and sonic preparations is shown in Fig. 4. The pattern of ATPase activity seen here with intact mitochondria most likely reflects that due to accumulation of the Ca^{2+} (see refs 5 and 8) and not that of the 'irreversible' ATPase seen in other mitochondrial preparations⁵. In

the present incubation conditions, sonic particles are unable to accumulate Ca^{2+} and this is reflected in the low ATPase activity seen with these preparations. Also in complete contrast with rat liver mitochondria⁴, the ADP-ATP exchange activity in intact ascites mitochondria is completely unaffected by all Ca^{2+} levels up to 350 nmol per mg protein.

A comparison of the present body of data (refs 7, 8 and submitted for publication) with that presented previously⁴⁻⁶ reveals that mitochondria from Ehrlich ascites tumour cells exhibit a response to Ca^{2+} which is distinctly different from that exhibited by all other mammalian mitochondria so far examined. A number of energy-linked reactions intimately linked to the process of oxidative phosphorylation change completely and irreversibly when mitochondria isolated from most normal mammalian tissue are exposed to excessive Ca^{2+} levels. Such changes are either absent or considerably dampened when tightly coupled mitochondria from Ehrlich ascites tumour cells are exposed to similar high levels of Ca^{2+} , which indicates that these mitochondria are atypical in their ability to tolerate extremely high concentrations of Ca^{2+} . Mitochondria from L1210 mouse ascites tumour cells have also been shown to tolerate high levels of Ca^{2+} (ref 12).

Important evidence reflecting this tolerance is shown in Fig. 1 where a complete lack of increase in the resting rate of state IV respiration was observed even after the accumulation of Ca^{2+} concentrations as high as 280 nmol per mg protein. In reactions such as the $^{32}\text{P}_i$ -ATP exchange where some change did occur, it was usually gradual and in no way reflected the marked change which occurs at Ca^{2+} levels of about 100–150 nmol per mg protein with, for example, rat liver mitochondria. Indeed, in the ascites preparations the response of the exchange to Ca^{2+} was practically identical in intact and sonic preparations.

The molecular events that occur when Ca^{2+} interacts with normal mammalian mitochondria to induce the (irreversible) modifications to the above energy-linked reactions are unclear. All the reactions are membrane-linked and show maximal sensitivity to Ca^{2+} when the mitochondria are most intact as revealed by the tightness of coupling of phosphorylation

Fig. 3 Influence of Ca^{2+} concentration on the $^{32}\text{P}_i$ -ATP exchange activity in intact and sonic mitochondria isolated from Ehrlich ascites tumour cells. The experimental conditions were exactly as described by Bygrave and Lehninger⁸. ●, Intact ascites mitochondria (43); ○, sonic ascites mitochondria (11); ▲, intact liver mitochondria (88). Values in parentheses indicate nmol $^{32}\text{P}_i$ exchange per min per mg mitochondrial protein in absence of added Ca^{2+} .

FIG. 4 Influence of Ca^{2+} concentration on ATPase (a) and ADP-ATP exchange (b) activities in intact and sonic mitochondria from Ehrlich ascites tumour cells. The experimental conditions were exactly as described by Bygrave and Lehninger⁹. ●, Intact mitochondria; ○, sonic mitochondria.

to respiration. Despite the uncertainties of the molecular events involved in uncoupling by Ca^{2+} it is quite clear that the Ca^{2+} -induced mechanism operating in normal mitochondria either does not exist or is grossly modified in mitochondria isolated from Ehrlich ascites tumour cells.

A second significant feature of our data is that the tumour mitochondria are not only tolerant to high levels of Ca^{2+} but also no longer respond to ADP with a respiratory jump. Thus phosphorylating respiration is prevented when these mitochondria are loaded with even small amounts of Ca^{2+} , a feature not seen in normal mitochondria (see ref. 1). This property is being studied in detail in our laboratory and most likely reflects an inhibition of adenine nucleotide translocation by Ca^{2+} in these tumour mitochondria. This is discussed elsewhere (submitted for publication).

Elsewhere we have advocated that Ca^{2+} movements between the cytoplasm and mitochondria form the basis of a means of controlling Ca^{2+} -sensitive cellular metabolic processes located in one or other of these two compartments¹³⁻¹⁸. Thus the unusual interactions of the Ehrlich ascites cell mitochondria with Ca^{2+} described here is of great interest. Although it is difficult to extrapolate information from *in vitro* experiments to *in vivo* events, the intriguing possibility exists that because mitochondria from Ehrlich ascites tumour cells can accumulate and maintain unusually high concentrations of Ca^{2+} without any apparent damage, they provide an environment in the cytoplasm consisting of a high $\text{Mg}^{2+}:\text{Ca}^{2+}$ ratio. In this way metabolic processes localised in the cytoplasm outside mitochondria such as glycolysis, protein synthesis and phospholipid synthesis, all of which are enhanced by an increase in this ratio¹⁸, proceed much faster than those occurring in other tissues, whose mitochondria are less tolerant to high concentrations of Ca^{2+} . Studies on the relation of these ideas to the growth and metabolic characteristics of various tumours are under way in this laboratory.

Response of mouse melanoma cells to melanocyte stimulating hormone

We have recently described a mouse melanoma cell line which responds to melanocyte stimulating hormone (MSH) with dramatic increases in tyrosinase activity and melanin content, as well as changes in cellular morphology and growth characteristics¹⁻³. The increase in pigmentation following exposure to MSH is shown in Fig. 1. Cyclic AMP or dibutyryl cyclic AMP may be substituted for MSH in eliciting these responses; consistent with other work suggesting that MSH acts through cyclic AMP in the control of pigmentation in vertebrates⁴⁻⁷. In our previous studies we used non-synchronised mouse melanoma cells grown in monolayer culture. Martin *et al.*⁸ have shown that synchronised mouse HTC cells respond to corticosteroids with increased tyrosine amino transferase synthesis in the late

FIG. 1 Effect of MSH on pigment formation by cultured melanoma cells. 10^6 cells were inoculated into each of 4 culture flasks; 10^{-7} M MSH was added to two of the flasks. After 4 d, the cells were collected, pooled, lysed in hypotonic buffer, and photographed. MSH-treated cells are on the left.

TABLE 1 Time periods for the cell cycle of colchicine-synchronised melanoma cells

Hours after release from colchicine	Phase
0-5	Mitosis
5-15	G1
15-25	S
24-45	G2
45-	Mitosis*

* Metaphase cells were counted to determine mitosis. At 45 h, approximately 25% of the cells were in metaphase, at 48 h more than 60% were in metaphase.

G1 and early S periods of the cell cycle; similarly, Buell and Fahey⁹ have shown, using a synchronised human lymphoid cell line, that immunoglobulins G and M are expressed in late G1 and S. We wished to investigate the effects of MSH on tyrosinase activity and endogenous cyclic AMP levels in synchronised cells to determine if there is a particular hormone-sensitive phase of the melanoma cell cycle. We report here that melanoma cells responded maximally to MSH with increased tyrosinase activity and cyclic AMP content during the G2 phase.

Cloudman S91 NCTC 3960 (CCL 53) mouse melanoma cells were obtained from the American Type Culture Collection, Cell Repository and maintained in monolayer culture as previously described². For a maximal response to MSH, cells were inoculated at 5×10^5 — 10×10^5 cells per 250 ml Falcon tissue culture flask and sub-cultured weekly. Under these conditions, the cells have a doubling time of approximately 48 h. If the cells are inoculated at a higher density or sub-cultured less frequently, they tend to show increased tyrosinase activity and melanin content in the absence of MSH and the response to the hormone is less marked.

Cells were synchronised by exposure to $0.015 \mu\text{g ml}^{-1}$ colchicine for 36 h, by which time most of the cells had reached metaphase. Metaphase cells were collected by manual shaking of the culture flasks, washed three times in complete medium free of colchicine, inoculated into 100 mm Falcon tissue culture Petri dishes at 10^6 cell per dish

FIG. 2 Incorporation of thymidine ³H-methyl, New England Nuclear 20 Ci mmol⁻¹ by synchronised melanoma cells. Cells were incubated with $1 \mu\text{Ci ml}^{-1}$ ³H-thymidine at 5 h intervals. After 5 h in thymidine, the cells were collected, precipitated with cold 5% trichloroacetic acid, filtered on to a 0.45μ Millipore filter, and washed with 30 ml 5% trichloroacetic acid containing an excess of non-radioactive thymidine. The filters were dried in air and counted in a liquid scintillation counter. The points are averages of duplicate culture flasks.

in 10 ml medium, and incubated at 37° C in a gassed, humidified incubator. The time periods for the various phases of the cell cycle were determined by the methods of Martin *et al.*⁸ Tyrosinase activity was assayed for cells *in situ* as previously described².

Cyclic AMP was measured by modifying the method of Brown *et al.*¹⁰: cyclic AMP binding protein from calf adrenals was further purified on a DEAE-cellulose column so as to be free of phosphodiesterase activity. Theophylline was found to increase the background in the binding assay and was omitted from the reaction mix. Two different procedures were followed to extract cyclic AMP from the cells

FIG. 3 Tyrosinase activity in synchronised melanoma cells. Cells were incubated with or without 10^{-7} M MSH which was added at the times indicated by arrows. 3, 5-³H-L-tyrosine (New England Nuclear 20 Ci mmol⁻¹) was added at $1 \mu\text{Ci ml}^{-1}$ to control and MSH-treated cultures at the same times that MSH was added. ³H₂O formation was measured to assay tyrosinase activity. Each point represents the ³H₂O formed h⁻¹ during the various time intervals. Zero time is when the cells were released from colchicine. The points are averages of duplicate culture flasks. X---X, Control; ●—●, MSH treated.

(see legends to Fig. 4 and Table 2) but the results were essentially the same regardless of which was used.

The time periods for the various phases of the cell cycle are shown in Table 1. The incorporation of ³H-thymidine into DNA was used to monitor the S phase (Fig. 2), and metaphase cells were counted to determine mitosis. The periods were the same whether or not MSH was added to the culture medium. MSH (10^{-7} M) was added to the cells at various times after release from the colchicine block in metaphase, and tyrosinase activity and endogenous cyclic AMP levels were followed in control and MSH-treated cells. The experiments were performed at least twice with similar results each time.

Tyrosinase activity was assayed by measuring ³H₂O released into the medium by cells incubated with 3,5, ³H-L-

TABLE 2 Cyclic AMP levels in synchronised cells following rapid extraction technique*

Time of cyclicAMP Extraction	pmol cyclicAMP per 2 × 10 ⁶ cells			
	Control Experiment	Average	MSH-treated Experiment	Average
<i>t</i> = 3 h	(1) 2.8 (2) 3.2	3.0	(1) 4.0 (2) 6.4	5.1
<i>t</i> = 12 h	(1) 2.8 (2) 4.8	3.8	(1) 3.2 (2) 4.8	4.0
<i>t</i> = 24 h	(1) 0.8 (2) 1.6	1.2	(1) 5.4 (2) 25.0	15.2
<i>t</i> = 30 h	(1) 2.0 (2) 1.6	1.8	(1) 41.0 (2) 45.0	43.0
<i>t</i> = 36 h	(1) 2.0 (2) 3.6 (3) 4.2	3.3	(1) 41.0 (2) 65.0 (3) 37.0	48.0
<i>t</i> = 48 h	(1) 2.4 (2) 3.0 (3) 3.4	2.9	(1) 25.0 (2) 45.0 (3) 35.0	35.0

* Cells were incubated as described and 10⁻⁷ M MSH was added 30 min before each sampling. Culture medium was removed by aspiration, the cells were rinsed gently with 2 ml Hanks' balanced salt solution, and ice-cold ethanol-0.2 N HCl was added to the cells with a Pasteur pipette. Removal of medium and addition of ethanol-HCl took less than 10 s. The cells were then placed at -10° C for at least 24 h and thereafter treated as described in legend to Fig. 4. The extracts were diluted in order to measure 0.2 to 5.0 pmol cyclic AMP per assay. The growth medium alone incubated in the presence or absence of MSH or with 100 pmol of added cyclic AMP contributed negligible amounts of cyclic AMP by this extraction procedure.

tyrosine. (Fig. 3a-f) Although the additions of MSH were staggered at 5 h intervals from 0-25 h, the hormone-mediated response was always maximal in the G2 phase of the cycle.

Cyclic AMP was measured at each time point following 30 min of exposure to MSH (Fig. 4 and Table 2). Although MSH increased cyclic AMP levels throughout the cell cycle, there was a dramatic rise over control values in the G2 phase of the cycle, 30-40 h after colchicine release. Control values changed very little throughout the cycle. MSH also caused an increase in cyclic AMP released to the culture medium by the cells (Table 3). The sharp increase in cyclic AMP levels in G2 seemed to precede the increase in tyrosinase activity, consistent with previous evidence that cyclic AMP is an intracellular mediator in the MSH response.

Two control experiments not shown here bear on the above results. First, when tyrosinase activity was measured in homogenates of collected cells, the results closely paralleled those obtained by measuring ³H₂O released to the medium. Thus the lag periods observed in the experiments presented here were not due to a lag in the uptake of ³H-tyrosine

TABLE 3 Cyclic AMP levels in the culture medium*

Treatment of medium†	pmol cyclic AMP per 10 ml
Without cells and without MSH	Experiment 1 < 0.1 2 < 0.1
Without cells, MSH added 30 min before sampling	Experiment 1 < 0.1 2 < 0.1
With cells and without MSH	Experiment 1 < 4 2 < 4
With cells, MSH added 30 min before sampling	Experiment 1 56 2 72

* Constituents of the culture medium were listed previously². Cells were released from colchicine and 0.25 ml medium was removed after 42 h incubation at 37° C. A sample of 2 ml ice cold ethanol-0.2 N HCl was added, and the mixture was placed at -10° C. After 24 h the mixtures were centrifuged and thereafter treated as in legend to Fig. 4. The extracts were diluted as described in legend to Table 2.

† All media were incubated for 42 h.

by the cells or to a lag in the release of ³H₂O to the medium. Second, colchicine, added again after the cells had passed through the initial mitosis, did not influence the results, providing additional evidence that the cells responded in the G2 phase.

When non-synchronised cells were treated with MSH, a rise in tyrosinase activity could be detected after a lag period of 6-9 h (ref. 3). The lag period with synchronised cells can, however, be as long as 35 h, depending when in the cell cycle MSH is added (Fig. 3). These results can be explained if it is assumed that in non-synchronised populations, the initial rise in tyrosinase activity takes place in cells that are in the G2 phase of their cycle.

Chen *et al.*⁵ have provided evidence that both MSH and cyclic AMP induce the differentiation of melanoblasts into melanocytes in organ cultures of caudal fins from xanthic goldfish. The melanoblasts are inducible shortly preceding mitosis, which may indicate that these cells are also most sensitive to MSH in the G2 phase. This result raises the possibility that vertebrate melanocytes are, in general, responsive to MSH in G2, an hypothesis which awaits further experimentation.

The relationship of the phase of the cell cycle to cellular phenotypic expression is as yet poorly understood. Varga *et al.*¹¹ have, however, recently provided evidence which explains why the melanoma cells respond to MSH only in the G2 phase. Using ¹²⁵I-labelled MSH as a tracer, they found that the cells are able to bind the hormone to their plasma membranes only in the G2 phase; there is little or no binding in G1 or S. Apparently MSH-receptors are available only in G2. Thus the MSH-mediated rise in intracellular cyclic AMP concentration is restricted to the G2 phase because this is the only time when the hormone can bind to the cells and stimulate membrane-bound adenyl

Fig. 4 Cyclic AMP levels in synchronised melanoma cells. Cells were incubated as described and 10⁻⁷ M MSH was added 30 min before each sampling. The wash procedure took 10 min and all operations were at 4° C. Growth medium was removed, cold Hanks, balanced salt solution was added, the cells were collected with a rubber policeman, washed three times in Hanks' by centrifugation, and cold ethanol containing 0.2 N HCl was added to extract cyclic AMP. After at least 24 h at -10° C the extracts were centrifuged, the supernatants removed, the pellets washed with additional ethanol-HCl, the supernatants pooled, dried *in vacuo*, and cyclic AMP measured by the method of Brown *et al.*¹⁰. Known amounts of cyclic AMP were added to aliquots of each extract as internal standards. Recovery of the standards was routinely more than 90%. The growth medium alone incubated in the presence or absence of MSH or with 100 p mol of added cyclic AMP contributed negligible amounts of cyclic AMP by this extraction procedure. The pellets were dissolved with 0.1 N NaOH and protein was estimated by the Lowry method. The points are averages of duplicate culture flasks ×-×, control; ● MSH treated.

cyclase. Presumably the increased cyclic AMP concentration then results in increased tyrosinase activity.

We do not yet know if the increase in tyrosinase activity in cells exposed to MSH is due to new synthesis of tyrosinase molecules or activation of pre-existing molecules. Localisation of the melanoma cell response to MSH in the G2 phase, however, should be helpful in the identification of the molecular intermediates involved.

Stimulation of tumour cell dissemination by raised temperature (42°C) in rats with transplanted Yoshida tumours

HYPERTHERMIA, that is, temperatures $\geq 40^\circ\text{C}$, may have a selective destructive effect on some types of cancer cells^{1,2}, and sporadic attempts have been made to treat human cancer by raised temperatures¹⁻³. Rossi-Fanelli and colleagues have demonstrated a selective and irreversible inhibition of metabolism in a variety of tumour cells at 42°C , whereas normal cells were unaffected^{1,4,5}. These workers obtained histological regression of malignant limb tumours in patients treated by regional perfusion with prewarmed blood¹. More effective and controlled methods for inducing hyperthermia⁶, and reports that the action of cytotoxic drugs can be potentiated by hyperthermia^{7,8}, have further stimulated interest in this approach to the treatment of human malignant tumours.

Little precise information is available on optimal conditions of heating, susceptibility of various tumours, and relative effectiveness of locally applied heat compared with total body heating. Some of these problems have previously been investigated using the VX2 carcinoma in the rabbit⁹⁻¹¹, and we now report observations on the behaviour of the Yoshida tumour in response to elevated temperatures *in vitro* and *in vivo*, with particular reference to the unexpected finding of stimulation of malignant cell dissemination by inadequate heating of implanted tumours at 42°C .

In the present work, the solid form of the transplantable Yoshida tumour¹² in the rat was used. The tumour was maintained by periodic transfer of 0.1 ml (100 mg) tumour homogenate by trocar superficially into the muscle of the hind leg in outbred Wistar rats of both sexes fed an *ad libitum* diet, and weighing 200-250 g. The tumours became palpable after 6 d and increased in volume exponentially until 11 d, when the growth rate decreased in accordance with the Gompertz function for solid tumours. The animals died at 26 ± 3.1 d (260 rats) following inoculation, when the primary tumour volume was approximately 100 ml.

The sensitivity of the Yoshida cells *in vitro* to increased temperature was assessed by conventional Warburg manometry, using 3.0 ml Krebs-Ringer-phosphate buffer, pH 7.40, containing 0.013 M sodium succinate with air as the gas phase, and 0.2 ml 10% KOH in the centre well (respiration); for anaerobic glycolysis the suspending buffer was 3.2 ml Krebs-Ringer-bicarbonate-phosphate⁴, pH 7.40, containing glucose (2 g l^{-1}), with a gas phase of 95% N_2 and 5% CO_2 . At temperatures above 41°C , there was depression of both respiration and glycolysis. At 42°C , irreversible damage to the cells occurred after 4 h, as indicated by cessation of O_2 uptake and CO_2 production, failure to respire or glycolyse on transfer to fresh incubation buffer at 38.0°C , and failure to produce tumours when transplanted into rats. On the basis of these results, 42°C was selected as the most suitable temperature to use for therapy of this tumour. Above 42°C , more rapid inhibition of respiration and glycolysis occurred, but the differential heat sensitivity between cancer cells and normal cells is diminished¹³, and subject tolerance in animals and in humans dictates that the therapeutic temperature range in heated tumours is $41-42^\circ\text{C}$ ¹⁰.

Figure 1 illustrates the temperature profiles obtained when tumour-bearing rats were treated by immersion of the affected limb in a waterbath to maintain an intra-tumour temperature of 42°C for 1 h. It was not possible to achieve this without the animal's central body temperature rising to an average in excess of 41.5°C over the 60 min therapy period. The rats did not tolerate this elevated temperature; of 167 rats so treated, 151 died during heating or within

Fig. 1 Tumour and central body (core) temperature profiles for a rat treated by immersion of the tumour-bearing limb in a waterbath at 43°C . The tumours were treated on the eighth day after inoculation into the hind limb when the volume was 10.3 ± 1.3 ml, and there was no necrosis present. The temperature monitoring probes were inserted under Nembutal anaesthesia, and temperatures were measured by multi-channel direct reading electric thermometers (Model 3 GID, Light Laboratories, Brighton). Temperatures were recorded from opposite poles of the tumour (intratumour I and II), from the abdomen and rectum. The rats were heated in groups of four, and during and immediately following therapy each animal was given 1 ml 4% dextrose-0.18% NaCl solution (at 42°C) to replace fluid loss. Temperature: X, bath; O, intratumour I; ●, intratumour II; □, intra-abdominal; ▲, rectal.

FIG. 2 Probit transformation for % mortality in a series of 200-250 g rats subjected to hyperthermia. The hind-quarters of the normal animals were placed in the water-bath, and the temperature in the muscle of the immersed limbs maintained at 42°C for one hour; the tumour-bearing rats were heated as detailed in the legend to Fig. 1. The average body temperature over the heating period was adjusted to the nearest 0.1°C. At each temperature point on the curve for normal rats there were at least eight animals with thirty animals at the 42.0°C point (total number of rats heated = 82), while for the tumour-bearing series there were at least twelve animals at each temperature point, and at 41.9°C and above there were at least thirty animals per point (total number of rats heated = 167). ○, Normal; ●, tumour-bearing rats.

the following 24 hours (survival rate for the heating = 9.6%). One rat survived for three days and nine died at 6-12 d following heating; the remaining six survivors were electively killed for pathological examination at 2-6 d after hyperthermia. As indicated in Fig. 2, the survival rate decreased rapidly when body temperatures in excess of 41.5°C were maintained for 1 h, and there was no difference in susceptibility to heat between normal rats and tumour-bearing animals. A body temperature just over 41.6°C represented the 50% lethal dose of heat, and few rats survived an intra-abdominal temperature of 42.0°C for 60 min.

There was no restraint of tumour growth and no inhibition of respiration after heating. Anaerobic glycolysis was significantly reduced immediately after heating, but returned to control values within 3 d. After hyperthermia, the tumours were oedematous and dark red in colour, and showed little microscopic evidence of cell destruction. These changes have been described previously for inadequately-heated VX2 tumours in the rabbit¹¹. In the animals that lived longer than 24 h, the mean survival time was 7.9 ± 2.5 d after hyperthermia, that is the rats died at 15.9 ± 2.5 d after transplantation, which was significantly less than the survival time in untreated animals ($P < 0.001$). Non-tumour-bearing rats that survived the hyperthermia had a normal life span.

Following implantation into the leg, the Yoshida tumour infiltrated muscle and other tissues, bone and the overlying skin. Later there was direct spread into the muscles of the

pelvis and posterior abdominal wall. From the nineteenth day after implantation, there was tumour in the retroperitoneal tissues in 38.7% of the animals (Fig. 3). In some rats the tumour had formed a large mass in the posterior abdominal wall surrounding and infiltrating both ureters. The perinephric and (or) peri-adrenal fat was infiltrated, and in advanced cases tumour had spread from the mesentery into the wall of the small intestine.

There was spread of tumour to the iliac lymph nodes by the ninth day, and later to the intra-abdominal para-aortic nodes. Tumour was observed in the upper para-aortic nodes at the level of the coeliac axis from the fourteenth day onwards in 32.4% of animals (Fig. 3). In animals with advanced tumours, the deep cervical lymph nodes adjacent to the thymus were involved, and in some, tumour had spread into surrounding fat and into the thymus.

Distant blood-borne metastases were uncommon in that pulmonary tumour emboli (Fig. 4) were observed in only two of ninety-one rats at 22 and 27 d after implantation, respectively. Involvement of the heart was commoner, and tumour was present in the myocardium in seventeen of sixty-nine rats (24.6%) with 13 to 32-d-old tumours (Fig. 3).

The liver and brain were not involved in any of the control animals.

The sixteen animals which survived heating at 42°C for 24 h or longer showed a more rapid dissemination of tumour than did unheated or sham-heated controls. This applied to direct, lymphatic, and blood-borne spread of the tumour (Fig. 3). Involvement of the retroperitoneal tissues occurred earlier, and with a significantly increased incidence, in the heated compared with the control series of animals over the same period (10-20 d following tumour implantation). Similarly, upper para-aortic lymph node involvement was observed earlier in the heated animals. Myocardial involvement was not premature, but occurred in a greater proportion of heated rats in comparison with the controls. Pulmonary involvement by tumour was observed in three of the sixteen heated rats, a much higher incidence than that in the controls. In two animals at 14 and 15 d following tumour implantation, there were multiple pulmonary emboli, and in the third, the lung parenchyma was extensively involved from the hilar aspect by mediastinal tumour which also involved the heart.

A further distinction between the control and test rats was the involvement of the portal tracts of the liver in two of the heated animals at 14 and 15 d, respectively, after tumour implantation (Fig. 5).

To exclude the possibility that manipulation of the animals and insertion of thermosensor needles into the tumour during heating might adversely affect spread of the tumour, a group of eighteen rats with 8-d tumours was heated in a bath at body temperature (38°C) for 2 h with needle probes inserted into the tumour. These sham-heated rats survived the procedure without loss and seven were killed at the fifteenth day, ten at the twenty-second day, and the remaining animal at the twenty-ninth day following tumour implantation. *Post mortem* examination of these animals showed a similar pattern of tumour spread in relation to the duration of the tumour implant as that observed in the control series (Fig. 3).

With various tumours transplanted subcutaneously in rats^{13,14} and mice^{15,16}, other workers have shown that the destructive effects of hyperthermia on susceptible tumours *in vivo* depend upon both the degree of heat and its duration. The response of the tumour can be expressed as an exponential type of curve in which approximately the same biological effect is obtained by halving the exposure time for each degree that the temperature increases above 42°C. To obtain regression in a variety of small tumours (maximum volume 2 ml) transplanted subcutaneously in rats, an exposure time of 60-90 min at 45°C is required^{13,14}.

The thermoregulatory mechanisms in rodents are less well-developed than those of man², and the animals are more sensitive to hyperpyrexia. The size of the Yoshida tumour (about 10 ml) in relation to the rat's body size implies that a considerable volume of blood (total blood volume in a

200 g rat = about 10 ml or 4.5% body weight¹⁷) is contained within the immersed tumour-bearing limb at any given instant. This precludes the maintenance of a temperature differential between tumour and normal body organs compatible with survival. A further difficulty encountered

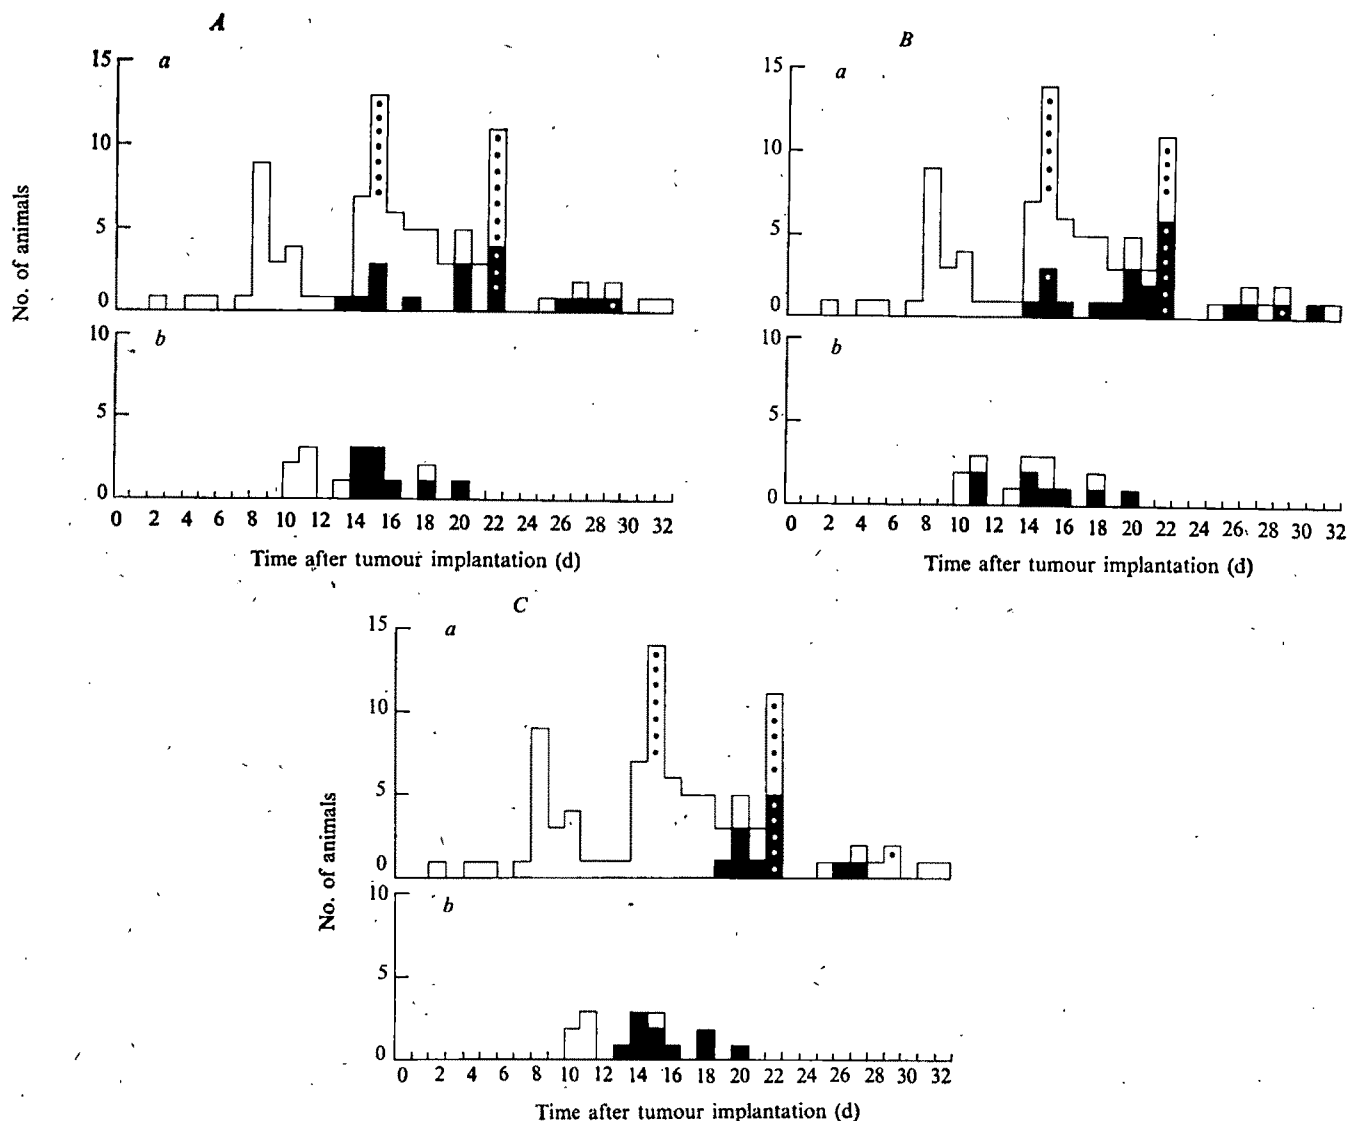

FIG 3 Incidence of tissue involvement by tumour. Examples illustrate spread by the direct, lymphatic and vascular routes. Animals were examined at post-mortem and in each of the 107 rats depicted in these frequency diagrams, the brain, abdominal and thoracic organs were examined histologically. The control and sham-heated animals were killed at intervals after implantation of the tumour to follow the time sequence of tumour spread by the various routes. All heated rats died by the twentieth day after implantation, with the exception of six animals that were electively killed to ascertain the pattern and extent of tumour spread prior to the fifteenth day. In animals that died during or within 24 h of heating, the post-mortem and histological findings did not differ from those in equivalent control rats.

In the case of the heart (A), control (a) and heated (b) animals showed myocardial involvement by tumour at the same time interval after implantation of the tumour (days 13 to 14). The incidence of heart involvement over the 10–20 d period in the heated animals was significantly higher than in the controls ($P < 0.01$). Note also that at the fifteenth day, none of the sham-heated animals showed myocardial involvement, and even at the twenty-second and twenty-ninth days, only four of eleven such animals had myocardial metastases. The incidence of myocardial involvement in the heated animals from the fourteenth to the twentieth days was nine out of ten. This suggests the increased incidence of myocardial involvement in the heated animals was not the result of mechanical factors associated with the heating procedure, such as the insertion of the needle thermistors into the tumour.

The para-aortic lymph nodes (B) at the level of the coeliac artery, and alongside the kidneys, were involved earlier in the heated animals (b) (eleventh day onwards) than in the controls (a) (fourteenth day onwards). The overall incidence over the 10–20 d period was thus higher in the heated group (50%) than in the controls (14.2%), and this difference is significant ($P < 0.02$). Insertion of the thermosensors again was without effect, and only one of seven sham-heated rats at 15 d (14.3%) had upper para-aortic lymph node involvement. In unheated and sham-heated animals with older tumours, the incidence of lymph node metastases was similar to that in heated animals at an earlier period after implantation and occurred in ten of twenty rats from the days 22–32 (50%).

The infiltration of retroperitoneal tissues (C) followed a similar pattern, with earlier involvement in the heated rats (b) at the thirteenth day compared with the nineteenth day in the controls (a), and with a significantly higher incidence in the 10–20 d period in the heated animals (62.5% compared with 7.7%, $P < 0.001$). In the heated rats showing this involvement, a large tumour mass was also present on the posterior abdominal wall. The tumour usually extended up to the lower pole of the kidneys, and often invaded the ureters. Again the sham-heated animals behaved as the other controls.

□, No tumour involvement; ■, tumour present; ●, sham-heated controls.

by previous workers has been inhomogeneous heating of tumours^{13,14}. In our work, a temperature difference of up to 0.5° C was detected by electrodes simultaneously inserted into the four quadrants of the same tumour during heating. The superficial temperature of the tumour was usually higher than the deep temperature. Two needles inserted into opposite poles to a depth of 1 cm gave a reliable guide to the temperature in the centre of the neoplasm. The depression of Yoshida tumour metabolism at 42° C *in vivo* was reversible, and together with the absence of histological damage and subsequent unrestrained increase in tumour volume, indicates that the hyperthermia was inadequate for tumour destruction.

The advanced stage of the disease in the rats that survived hyperthermia indicates that the heating accelerated dissemination of this tumour. The precise mechanisms involved are undetermined. Metastasis is a complex phenomenon comprising a sequence of at least five processes^{18,19}. The hyperdynamic state of the circulation at elevated temperature, and the local active hyperaemia, may predispose to increased 'showering' of tumour cells into the blood from the primary mass²⁰. It is now recognised, however, that there is no definite correlation between the presence of cancer cells in the blood *per se* and the development of metastases^{18,19}. Local hyperthermia may have changed the mobility of the cells of the primary tumour. Mondovi *et al.*²¹ recently described an increased antigenicity in Ehrlich ascites cells heated at 42.5° C *in vitro* for 1–3 h, and postulated that short exposure to raised temperatures caused some modification of the cell surface. The rise of central body temperature to more than 41.5° C may have altered the metabolic or biological properties of the tissues concerned

FIG. 4 Pulmonary tumour embolism in control rat killed 22 d after implantation of tumour into the leg. Note tumour cells occluding the lumen of a pulmonary vessel and spreading into the alveolar wall capillaries (arrow). This phenomenon was observed in only two rats in the large control series (ninety-one animals) at 22 and 27 d after tumour transplantation, respectively, but occurred in two of the sixteen heated rats dying at 14 and 15 d after implantation, respectively. Haematoxylin and eosin $\times 200$.

FIG. 5 Tumour infiltration of portal tract and sinusoids in liver of rat heated at 42° C for 1 h, 8 d after implantation of Yoshida tumour into the leg. Death occurred 6 d later. There was also metastatic tumour in the heart, and widespread tumour throughout the retroperitoneal tissues involving the bowel wall and renal parenchyma. Haematoxylin and eosin $\times 120$.

in metastatic distribution of the cancer—the so-called 'soil' originally discussed by Paget²². Histological examination is a relatively crude method of detecting the presence of metastases^{23,24}; it is therefore possible that the present results reflect stimulation of premature activity in Yoshida cells already present in metastatic sites at the time of heating. The appearance of metastases in the liver of two of the sixteen heated animals would seem to argue against this interpretation. A possible depression in the immune defence mechanisms of the host at increased body temperature¹⁰ leading to more rapid spread of the disease must also be borne in mind.

In our work, the Yoshida tumour behaved as a highly-malignant rapidly growing sarcoma, with a capacity for metastasis not commonly found in transplantable animal tumours, but more usually associated with malignant neoplasia in man¹⁹. Although the various factors controlling the selective localisation and development of secondary tumours have not yet been clearly defined, the pathogenesis of a given neoplasm is influenced by a balance operating between the growing tumour and the reaction of the host²⁵. Depending on the adequacy of heat application to the primary tumour, this balance can be altered to the benefit or detriment of the host. It has been claimed that hyperthermia is most effective against rapidly growing tumours of mesenchymal origin^{1,2,8,15}. In the light of our present experiences, however, the possible hazards of inadequate heating of malignant tumours in animals and in man must be considered.

Recovery of immune system after cigarette smoking

RECENT evidence has shown that the immune response in human cigarette smokers¹ and in mice chronically exposed to fresh cigarette smoke²⁻⁴ is impaired. It has been proposed that depressed immunity in smokers may therefore be involved in the increased prevalence of respiratory infection and neoplasia associated with this habit⁵.

In this laboratory, mice exposed to cigarette smoke show a depression in the development of antibody-producing cells in the spleen, the lungs and their draining lymph nodes, after the introduction of sheep erythrocytes (SRBC) into the respiratory system^{2,3}. Both primary and secondary responses are depressed. This is accompanied by a loss in the phytohaemagglutinin (PHA) responsiveness of the lymphocytes, particularly in the lymph nodes of the respiratory tract⁴. Moreover, the smoke-exposed mice developed an increased number of macrophages in the lungs⁶ similar to that observed in human smokers⁷. Although an infiltration

of lymphocytes into the lungs also occurs in mice soon after the start of exposure to smoke, it is only transient⁸.

The lungs and livers of mice exposed to the smoke also show elevated activity of aryl hydrocarbon hydroxylase⁹, an enzyme which also exhibits high activity in the tissues of human smokers⁹. In other experiments¹⁰, alveolar macrophages lavaged from mice immediately after exposure to smoke exhibited depressed viability, and surviving cells showed altered metabolic activity, indicating penetration of active components of cigarette smoke deep into the lungs. Furthermore, histological sections of lungs from these exposed animals show tar-laden macrophages in the alveoli.

The impairment in the humoral immune response appears to be more complex than just a depression in the amount of immunogen absorbed through the respiratory tract. The antibody-producing cell response at a distant site, the spleen, is less sensitive to the effects of cigarette smoke than sites associated with the respiratory system². A defect in lymphocyte function, as indicated by their impaired responsiveness to PHA (ref. 3), provides a possible mechanism.

While it is important to determine the severity and the mechanisms by which immunosuppression is induced by cigarette smoke exposure, it is equally important to investigate whether or not these effects are reversible on termination of cigarette smoking. We present evidence here which indicates recovery of humoral immunity on termination of cigarette smoke inhalation.

Groups of mice were exposed to fresh cigarette smoke in a Hamburg II small animal smoking machine (Heinr. Borgwaldt, West Germany) on week days. Smoking conditions were as previously described². To measure the humoral immune response, mice were inoculated intratracheally with 10⁸ SRBC, and after 7 d the direct and indirect plaque-forming cells (PFC) in the spleen, the lungs and a pool of the mediastinal and cervical lymph nodes were determined by the Cunningham-Szenburg modification of the Jerne plaque technique as previously described². The

Fig. 1 Recovery of the immune responses of mice to sheep erythrocytes following the cessation of smoking. The plaque-forming cell response (PFCR) before (S), and after, Ex, cessation of cigarette smoke exposure is shown (mean \pm s.e.) as a % of age-matched controls C. a, Lung; b, lymph node; c, spleen.

number of PFC per 10^6 leukocytes was calculated. About 10^8 , 10^7 and 10^6 leukocytes (predominantly lymphocytes) per cell preparation were obtained from the spleen, lymph nodes and lung respectively. No difference between the number of leukocytes in the cell preparations from normal mice and mice exposed to smoke could be detected. The assay time used coincides with the peak primary response of normal mice. Groups of five to nine mice were used in all experiments and the significance of differences between groups was determined by Student's *t* test.

The direct PFC response in mice exposed to fresh cigarette smoke for 42 weeks (*S*), together with the response of mice exposed to fresh cigarette smoke for 42 weeks followed by a further 16 weeks during which time they were not exposed to smoke (*Ex*), are shown as % of age-matched controls (*C*) in Fig. 1. The control mice had an average of 21 PFC per 10^6 leukocytes in the lung, 80 PFC per 10^6 leukocytes in the lymph nodes and 10 PFC per 10^6 leukocytes in the spleen.

Control mice used here were not sham-smoked, as observations^{4,11} indicate that handling stress does not contribute significantly to the effects observed in the exposed mice.

The primary immune response in all organs was markedly depressed after 42 weeks smoke exposure compared with control animals (lungs, $P < 0.05$; lymph nodes, $P < 0.01$; spleen, $P < 0.05$). Sixteen weeks after the cessation of smoking the mice exhibited significantly increased direct PFC responses in the lungs ($P < 0.001$) and the lymph nodes draining the respiratory system ($P < 0.05$) when compared to animals at the end of the 42 week exposure period. Although the average response in the spleen indicated recovery the results observed were extremely variable, with several of the animals still exhibiting low responses. The indirect PFC responses also showed a depression after 42 weeks' smoke exposure in all organs and a recovery 16 weeks after exposure to smoke ceased. The numbers of indirect PFC in the primary responses, however, were low.

The immune system in the respiratory tract exerts a protective function against infections^{12,13} and tumour development¹⁴⁻¹⁶. These diseases show increased prevalence rates in smoking mice^{11,17} and in human smokers¹⁸, but human epidemiological studies indicate that cessation of smoking progressively leads to a lowering of the risk of their development^{18,19}.

If the immune system of man reacts to cigarette smoke in a similar way to that of the mouse, as some data imply¹, the phenomenon of 'recovery' in the ex-smoker^{18,19} may be attributable, in part, to a similar restoration of immune function as that demonstrated here.

The lamp voltage used in experiments I and II, and for the lamps in the T-unit in experiment III, was 4.0 V.

learning as our ultimate goal, we have attempted to demonstrate associative learning with respect to optical stimuli in *Drosophila*. Here we report our first successful experiments.

Attempts to demonstrate spatial discrimination learning of *Drosophila* were reported by Murphey^{8,9} but later contradicted by Yeatman and Hirsch¹⁰. Recently Quinn, Harris and Benzer¹¹ have found conditioned behaviour in *Drosophila melanogaster* both with olfactory and visual discrimination. Götz (personal communication) has trained individual *Drosophila* with respect to light-dark stimuli. *Drosophila* strains wild type (Berlin) and *ebony* were kept on standard media at 22° C with a 12 h light: 12 h dark cycle. The flies used in the experiments were aged between 1 and 10 d after eclosion (No separation of male and female flies has been undertaken as yet). Because *ebony* have a higher activity in the maze used, experiments were performed with strain *ebony* unless otherwise stated.

The test apparatus (Fig. 1) is related in design to the T mazes used by Hadler¹². It rests horizontally on a table and is constructed entirely of plexiglas. The flies are placed in a starting container and can move freely into the 'training alley'. This consists of a tube 13 mm in diameter with two narrow funnels placed 3.5 and 7 cm respectively from the start. The funnels are constructed (Fig. 2) to provide a one-way passage for the flies. In front of each funnel is a plexiglas light conductor, connected to an Osram 2403 (6 V, 1 W) lamp equipped with plexiglas coloured filters (Röhm and Haas No. 300 and 627). Except for the front faces, the light conductors are covered with black tubing. The flies can thus be exposed to a blue or a yellow light, most intensely at the exit of the funnels. After having passed through the training alley the animals reach a 'T-unit' where they can choose to proceed through a yellow or through a blue illuminated funnel constructed and illuminated exactly as in the training alley. After having passed through these funnels the flies are collected in two separate containers and counted conventionally.

Training is carried out with electroshocks. For this purpose the funnels in the training alley are equipped with tiny copper wires (Fig. 2) connected to the output of a pulse generator. The pulses have a duration of 1 ms with 80 V peak voltage at 80 ms intervals. If a fly touches two wires of opposite polarity, it experiences electrical shocks with currents of about 10 μ A. The animals clearly try to escape these electroshocks. The construction of the shocking device is the critical part of the apparatus. As recorded with a microammeter only about 30% of the animals, especially the smaller ones, can pass the funnel without being shocked.

In the basic experiment, the flies were exposed to an electroshock at only one of the funnels (either blue or yellow illumination) and the % of animals that passed the 'blue funnel' in the T-unit, relative to the total number that completed the run was determined. This was compared to the % measured without application of electroshocks, that is, the spontaneous distribution measured in a separate experiment in identical optical and geometrical conditions but with a new population of flies. To ensure true difference measurements, this control was always carried out immediately before the test run. Furthermore the apparatus was taken apart, washed with detergent and carefully dried between two different experiments, but not between the control and test runs. In this way slight changes in the apparatus after reassembly, which are reflected in the spontaneous tendency (see Table 1), cancel out in the difference between the two runs.

The experiments were carried out at room temperature. Wet filter papers placed in the counting containers helped to maintain an appropriate humidity for the flies and possibly served as attractant as well. Approximately 300 flies were placed in the starting container for each run. At the end of the run, after about 5 h, more than 50% had passed the T-maze. Except for the yellow and blue lamps, the experiments were carried out in the dark. If observation was necessary, overhead red safety lights (Philips TL 40W/15) were used.

For each run the number of animals having chosen the

TABLE 2 Statistical significance of results.

Strain	Electroshock at	Δ	t-Test	χ^2 -Test	Interpretation
Wild type	'yellow'	+10.7 \pm 3.4	$P < 0.01$	$P \ll 0.001$	Avoidance of 'yellow'
	'blue'	-17.6 \pm 5.2	$P < 0.01$	$P \ll 0.001$	Avoidance of 'blue'
<i>ebony</i>	'yellow'	+ 9.1 \pm 2.9	$P \ll 0.01$	$P \ll 0.001$	Avoidance of 'yellow'
	'blue'	-12.1 \pm 2.9	$P < 0.01$	$P \ll 0.001$	Avoidance of 'blue'
<i>ebony</i>	Funnel No. 1 (no lights in training alley)	+ 1.1 \pm 4.4	$P > 0.6$	$P > 0.5$	—

The first four experiments listed used the same arrangement of lights. The first funnel was illuminated with yellow light, the second with blue light. The lamp voltage for experiments with wild type is 3.2 V. *Ebony* is a phototactic mutant; a lamp voltage of 4.0 V was used in experiments with *ebony*. The last experiment listed used no lights in the training alley, but blue and yellow illumination of the funnels in the T-unit.

FIG. 2 Schematic drawing of the electroshock device. a, Pulse generator.

blue or yellow illuminated arm of the T-unit were counted and the % of 'blue' choices determined. As we have pointed out above, the experiments were performed as difference measurements between a population having experienced electroshocks associated with a particular optical stimulus and a population which had received no electroshocks. A conditioning index can thus be defined as

$$\Delta = (\text{choices})_{\text{shocked}} - (\% \text{ 'blue' choices})_{\text{control}}.$$

This difference is zero, if the animals do not learn. Avoidance of 'yellow' after electroshocks results in positive numbers, avoidance of 'blue' after electroshocks results in negative numbers.

For a series of these measurements the average of Δ and the standard deviation (not the standard deviation of the mean) was computed (Table 2). A *t*-test for significance of the differences ($\Delta \neq 0$) was performed. Although not quite appropriate, because it neglects the explicit performance of difference measurements, a χ^2 -test of the total number of flies within a series of experiments is listed as well.

Table 1 lists the results from four different sets of experiments. In the first set, the flies were exposed in the training alley to first the yellow light then the blue light. Electroshocks were applied at either the first or the second funnel. In experiment II the order of lights in the training alley, was reversed. In experiment III there were no lights in the training alley, but lights in the T-unit, and experiment IV was run in complete darkness. This last experiment was meant to demonstrate that, with the exception of the light stimuli, the apparatus is completely symmetrical; no right-left bias was observed.

Table 1 lists the number of animals counted in a single experiment and its corresponding control without electroshock. The data are representative of the experiments performed. (Their statistical significance is evaluated through Table 2.) The data suggest that positive learning, that is, association of the optical stimulus with electroshocks and subsequent avoidance of a similar optical environment occurs. The results of these experiments cannot be explained by sensitisation by electroshocks. Because of the symmetrical experimental design, electroshocks both at 'blue' and at 'yellow', a pseudolearning control is unnecessary. That it is indeed the optical stimulus which is being learned is suggested by experiments III and IV which are not significantly different from their respective controls.

Table 2 shows the averages of a number of experiments with wild type *Drosophila* (strain Berlin) and the mutant *ebony*. The data clearly demonstrate a positive learning behaviour both for avoidance of the yellow light stimuli and for avoidance of the blue light stimuli. Although the effects are not large, the deviation from zero of the difference between experiment and control is highly significant in all cases. A sign test yields a high degree of significance. Out of 46 experiments only two cases of 'masochism' were found,

while 44 cases indicated avoidance of the optical stimulus associated with the electroshock. In contrast, if the electroshock was not associated with a light stimulus (no lights in the training alley) no significant differences between experiment and control were found (Table 2).

The greater incidence of positive learning for the wild type in blue light probably results from a favourable relation between light intensity and physiological sensitivity in these circumstances. Further studies are necessary before more quantitative relationships can be established. It is to be expected though, that larger effects will be obtained if the flies are exposed to more than one training situation either at short intervals or on consecutive days.

It should be pointed out that the two light stimuli used in these experiments differ not only in colour but also in physiological rating. Thus, the experiments are not necessarily interpreted as proof of discrimination of the two colours¹¹. There is independent evidence for colour vision of *Drosophila* obtained by Schümperli¹³ as well as in this laboratory. However the data presented here are considered proof of associative learning in *Drosophila* with respect to optical stimuli.

Identification of chemicals of snail origin that attract *Schistosoma mansoni* miracidia

MEASURES to control schistosomiasis (bilharziasis) aimed at either the molluscan vector or the trematode's larval stages might be enhanced by a better understanding of the intricacies of how miracidia and cercariae find and penetrate hosts. Previous work from our laboratory identified chemicals from mammalian skin that initiated penetration responses by *Schistosoma mansoni* cercariae¹. Other earlier studies implicated amino acids and additional compounds as attractants of *S. mansoni* miracidia to the molluscan host, but did not show that these substances were derived from the snail². Subsequently, based on Neuhaus³ and C. A. Wright's⁴ indications that snails release substances into water that stimulate miracidia, several investigators⁵⁻⁸ have confirmed that snails 'condition' water making it stimulatory or attractive to miracidia. Wright and Ronald⁹ recently demonstrated that water conditioned by the snail *Lymnaea palustris* attracted miracidia of the rodent blood fluke, *Schistosomatum douthitti*, and that this snail-conditioned water (SCW) contained amino acids. Here we show that *Biomphalaria glabrata*, the molluscan vector of *S. mansoni*, the important parasite of humans, contributes amino acids

TABLE 1 Amino acids identified in snail-conditioned water.

Taurine = $0.054 \mu\text{mol l}^{-1}$;	
Urea = $2.51 \mu\text{mol l}^{-1}$.	

Data represent means of two assays, each on a separate preparation of SCW. Amino acid concentrations were determined from standards prepared in the residue from 500 ml of spring water.

to the aqueous environment, and that these, and possibly other substances elicit chemotactic and chemokinetic responses by miracidia of this parasite.

The schistosome and hosts were maintained as described^{1,2}. SCW was prepared by placing 100 snails (10 mm diameter minimum) in 500 ml of commercial spring water (Magnetic Springs Water Co., Los Angeles, California) for 2–3 h to minimise faecal output during the conditioning process, then rinsing with three 10 min changes of spring water to remove adherent materials. These snails were subsequently used to condition 500 ml of spring water for 18 h. No antibiotic was added to the spring water during conditioning to preclude the induction of amino acid release by the antibiotic. The snails were removed, the SCW filtered (0.45 μm pores), evaporated to 18.5 ml, acidified, and refiltered. The amino acid fraction was eluted from Dowex 50, evaporated to dryness, and taken up in 1.5 ml of 0.2 N sodium citrate buffer (pH 2.2) for analysis. Nineteen common amino acids were identified with an automated analyser (Table 1). No amino acid was detected in controls of 500 ml spring water (no snails) treated as above (three replicates). Two additional control samples were assayed similarly, except that a standard containing a known amount of each amino acid was added to the evaporated spring water. Neither amplification nor increase in numbers of the known peaks was detected. These results clearly demonstrated that the snails contributed amino acids to the water.

The stimulatory or attractive qualities of SCW before and after evaporation was tested by the method of Chernin⁷ and always gave an immediate, strongly positive response. As this bioassay neither yields quantitative data nor necessarily shows a chemotactic response, we devised a choice-system bioassay consisting of a rectangular chamber (37 \times 3 \times 2 cm deep) mounted on the stages of two stereoscopic microscopes. The chamber contained 25 ml spring water. Miracidia (1–4 h old) were added in 1 ml of spring water to the centre of the chamber. For 20 min, two observers simultaneously recorded the number of miracidia entering the 3 cm field of view from the mid-chamber region on each end of the chamber; entries from the distal ends of the chamber were disregarded. This experimental design minimised the number of miracidia in these data that might be 'trapped' by scoring only those that entered from the mid-chamber region. The diffusing chemical may have established an active zone beyond the field of view and in this way caused miracidia leaving the mid-chamber region of

the field of view to return to the source of the stimulus. Such a 'turnback' response indicates chemotaxis^{2,7}.

The time period began when 75 μl of substances to be tested were gently pipetted onto the surface at the centre of each field of view. Experiments were conducted in a darkened room at 22° C. Uniform, diffuse light was supplied by a 10 W neon tube centred 23 cm above the chamber's long axis. Preliminary experiments designed to standardise the system showed that this method gave a dynamic, quantitative analysis through direct observation of miracidial behaviour in the presence of both experimental and control substances.

Using this system, we demonstrated that the presence of SCW produced significantly more entries into the field of view than did spring water controls (Table 2). In addition, behavioural changes described by MacInnis² and by Chernin⁷ were exhibited by nearly all miracidia entering the field containing SCW, but rarely in the control. In other experiments concentrated SCW was prepared in agar blocks², then bioassayed in the chamber against agar made with spring water. At the end of five 10-min experiments with these agar blocks, the ratio of miracidia in the fields of view was 10:1 (experimental:control). These results clearly demonstrated that the presence of SCW not only attracted miracidia, but also kept more miracidia in the vicinity of the source of the stimulus.

To ascertain whether or not the amino acids identified in SCW could elicit responses by miracidia, a mixture of amino acids was prepared at concentrations equivalent to that determined to be present in SCW (Table 1, taurine and urea were omitted). This mixture was also assayed with the amino acid analyser, and the concentration of each amino acid shown to be essentially as noted in Table 1. Bioassay of this mixture (Table 2) demonstrated that the amounts of amino acids produced by snails increased the number of entries into the field of view. This mixture appeared slightly, but not significantly, more effective than the SCW assayed (Table 2, $P > 0.1$). This difference might be explained by the fact that the size of snails used to prepare SCW in these trials was somewhat smaller than those used to prepare the SCW for chemical analysis. Such an interpretation is consistent with Chernin's results with SCW from snails of different sizes⁷.

Table 2 also shows the results of double control experiments in which 75 μl of spring water were added to each end of the chamber. Comparison of these results with those of the controls run with SCW or the amino acid mixture demonstrated that the presence of the SCW or amino acids not only increased entries into the field of view, but also reduced the number of entries in the field opposite the chemicals. Such results indicate that amino acids and other chemicals released by snails cause miracidia to localise preferentially in

TABLE 2 Bioassay of 75 μl of snail-conditioned water and of an amino acid mixture equivalent to the amino acids determined to be present in it (Table 1).

No., Number of experiments (50 miracidia per experiment in 25 ml spring water); control is 75 μl of spring water; in the double control experiments 75 μl of spring water were added to each end of the chamber. Replicates were accomplished by alternating experimental and control additives in each end of the chamber. Probability, P , calculated from Student's t test.

the region of the stimulant, and thus enhance the chances of a miracidium encountering a snail.

SCW contains many components other than amino acids. Preliminary experiments with a peptide fraction (obtained from SCW by the method of Nakano and Yamamoto¹⁰) showed no attraction over a distance, but did elicit slight modifications of the normal miracidial swimming pattern. Preliminary analyses of SCW (transesterified with methyl alcohol) by gas-liquid chromatography indicated the presence of at least six peaks whose identity and ability to stimulate miracidia have not yet been resolved. Our results with the amino acid mixture, and those of Shiff and Kriel⁶, who passed their SCW through a 'mixed-bed resin', suggest, but do not preclude the possibility, that inorganic ions need not contribute to attraction of miracidia.

Although amino acids or other substances may leach out of the mucus and faeces of the snails, amino acids also may be released from the epithelial cells of snails in an osmoregulatory function as discussed by Potts¹¹. It may be noted that Chernin⁷ reported that faeces of *B. glabrata* were not attractive to *S. mansoni* miracidia in the bioassay. C. A. Wright⁴ found that faeces did stimulate miracidia, but such results must be interpreted with caution as any material removed from SCW may absorb sufficient amounts of the stimulative substances to elicit a response. Our results clearly proved, however, that the amino acids produced by snail hosts can serve as attractants for miracidia. How can such results be used to improve methods of controlling bilharziasis and other pathogens?

It is possible that amino acids (and other, as yet unidentified components of SCW) produced by snails, or released from plant materials during feeding by snails, keep miracidia, cercariae and snails within a limited focus helpful to completion of their life cycles. Attraction of snails to amino acids was proposed by MacInnis, but has not yet been tested².

Incorporation of attractants such as amino acids into larvacides and molluscicides, possibly into easily dispersed materials such as proposed by N. F. Cardarelli (United States Patent No. 3,417,181, December 17, 1968) may be used to attract both parasite and vector into a zone of effective pharmacopoeia. Alternatively, they might be attracted to particles containing insoluble poisons (which would be less dangerous to the ecological aspects of the environment) and induced in the case of the mollusc to feed upon such materials, or, in the case of the larval trematodes, to waste their energies and secretions in futile attempts to penetrate particles emanating attractants which also initiate penetration responses^{2,7}. Amino acids and other substances released from processed plant material used as a schistosomacide or molluscicide, might also contribute to the success of such material when used in nature^{12,13}. These possibilities, in view of the fact that the widely used molluscicide sodium pentachlorophenate is a repellent to snails¹⁴, further provide support and impetus for future investigations on artificial or natural larvacides and molluscicides in combination with attractants.

Stereopsis by binocular delay

HERE I report results which reveal a new form of binocular stereopsis sensitive to delays between the arrival of common input to both eyes instead of retinal disparity.

Until the work of Julesz¹ monocular form detection was commonly believed to be a prerequisite for the detection of binocular retinal disparity and so for stereopsis. Julesz showed monocular form detection not to be necessary by demonstrating cyclopean perception of targets in depth with random dot stereograms. Neither member of the stereogram pair conveyed any monocular information about the target. A continuous analogue of Julesz's random stereogram method is used in the present observations to show that neither monocular form nor binocular disparity is necessary for stereopsis.

Figure 1 shows that when both eyes are fixated on a target, each sees different areas of the foreground and background, a fact established by Hering's² demonstration of the Law of Identical Visual Directions. It follows that as the eyes rove at a constant fixation distance, they encounter the same background texture at different times, the delay being a function of the eyes' rate of traverse, the distance of the target and the distance of the background.

When they move from left to right, the left eye encounters parts of the background before the right. In the foreground, the situation is reversed. The right eye leads and the left trails. Both eyes encounter whatever is at the fixation distance at exactly the same time.

The apparatus presented each eye with some common (target) input at the same time, and some common (background) input at different times. Each eye viewed a point-plotting oscilloscope (Tektronix 602, P15 phosphor) controlled by a PDP8-E computer via specially designed interfaces. (For details see Ross and Hogben³.) Polarised filters shield each eye from the other's view. The first target was an outline square (2 cm × 2 cm), presented to each eye simultaneously in repeated 10 ms bursts, at a rate above critical flicker fusion. The background was a continuous (or dynamic⁴) noise stream of single dots, distributed uniformly at random over the whole of an 8 cm × 8 cm display area, within which the target was centred. Dots were plotted at a rate of about 9 ms⁻¹ whenever the target was not being plotted, so that each eye seemed to see a field of many dots, like a snowstorm, the distribution continuously changing. Each dot in the stream was shown to both eyes at the same rate, but at different times. One stream, so to speak, lagged behind the other.

It should be noted that delay here does not produce an effective disparity, as it would if successive points fell in order along a horizontal line, because points fall randomly in two dimensions. Effective disparity due to delay has been proposed as an explanation for the Pulfrich phenomenon.

When the delay between the eyes is below about 50 ms, the binocular view reveals a target roughly in the same plane as the noise field. When it is above about 70 ms, the noise field recedes well behind the target. The effect is vivid, and unmistakable, even for some observers with poor stereopsis for displays based on disparity. Between 50 and

FIG. 1 View of each eye at different times. A, B, C and D are points in the background; α , β , γ and δ are points in the foreground. Because of motion parallax, rate of transverse over the background is more rapid than over the foreground.

70 ms, the situation is ambiguous, the background being seen alternately in the plane of the target, or behind.

Delay was pitted against disparity by shifting dots in the noise stream to give them a crossed disparity. Below 50 ms delay, disparity is dominant, the noise plane being seen in front of the target, and transparent. Above 70 ms, delay is dominant, the noise plane now lying behind the target and looking opaque. In the 50–70 ms range, the background alternates from in front to behind. The alternation does not seem amenable to voluntary control.

The monocular contour provided by the outline square can be eliminated by an analogue of the Julesz method, mentioned above. Points to be plotted to both eyes are generated at random within the 8 cm \times 8 cm available display area. Points falling within a central square area (2 cm \times 2 cm) are plotted, forthwith and simultaneously to both eyes. Points falling outside the central square area are plotted immediately to one eye, and buffered, to be displayed, at the same rate, but later, to the other eye. Each eye sees the same points at the same rate and distributed uniformly at random over the whole display area. All that differs is the time of presentation. There is no monocular distinction between target and background. The only mechanism which could determine that there was a distinction is one which had access to both fields of view, and which could register and recognise differences between them.

When delay in the background exceeds 70 ms, the target is seen standing in depth, in front of the background. The edges of the target are not so sharply delineated as when disparity is used to define a target but, as with disparity, there is no apparent motion of dots across the boundaries of the target. (See Julesz¹, and Ross and Hogben³, for comparable effects with disparity). Of course, there is no similar confinement of motion within either monocular view. At delays below 50 ms, the target can be distinguished from the background, but not clearly and only faintly at differential depth.

When the background is composed of independent sets of points, so as to produce rivalry, both targets, the monocularly visible and the monocularly invisible, sit embedded in, rather than in front of a nebulous surround, thus eliminating the possibility that delay induces complete or partial rivalry and has its effect accordingly.

The observations reported here show that retinal disparity determines relative depth when input is received by the two eyes within a span of 50 ms, confirming the value determined by Ross and Hogben³, for short-term memory in stereopsis. More importantly they show that delay alone can determine relative depth when the span for disparity is exceeded. It can do so even in the absence of monocular information about form, as can disparity.

The upper limit for delay has not yet been determined precisely, but indications are that it is near 2 s. At delays beyond 2 s the target is visible, but the background looks rivalrous, has the nebosity characteristic of independent random point streams and is no longer a plane behind the target.

Many observational details fit the suggestion that the visual system handles common input with binocular delay as if it had been generated by eye movements (see Fig. 1). When the left eye receives input first, the background streams from right to left, as if the eyes were sweeping left to right. The target appears stationary. Direction of background movement is reversed when the right eye receives input before the left. At certain delays, there is also a lacy plane in front of the target, with movement always in a direction opposite to that on the back plane. As Fig. 1 shows, the eye leading in seeing background texture trails in seeing foreground texture.

Retinal disparity provides a fine sense of depth within a narrow spatial range, Panum's fusional area, and a narrow temporal span of about 50 ms (see Ross and Hogben³). We may speak of a fusional area and a fusional span, both limiting disparity in stereopsis. The results reported show that the visual system can also deduce relative depth, and direction of movement, from common input received at binocular delays beyond 50 ms. There thus seem to exist two binocular systems for depth, one operating within narrow spatial and temporal limits, to give fine resolution around fixation, and the other operating outside the temporal limits of the first to give a coarse indication of the structure of background and foreground space.

This research is supported by a grant from the Australian Research Grants Committee. I thank A. Sala, who designed much of the apparatus, and J. H. Hogben, who helped in programming and in clarifying the displays.

science on television

Visceral learning

John Wilson

DR NEAL MILLER, of Rockefeller University, New York, believes that we can learn to control our blood pressure, and other regular bodily functions, just as we control the movement of our limbs—if only we try hard enough. With my overdraft in mind, I thought that my bank manager might benefit from the technique so when Yorkshire Television asked "What's Visceral Learning Anyway?" I settled back to learn the answer.

It was not long in coming. Before the opening credits had rolled there was Dr Miller's most successful hypertensive patient, a woman, telling all. She did not know how she did it, she said, it just happened (or rather more accurately, it later transpired that she provided explanations, such as thoughts of old Bogart movies, which her doctor discounted).

Having given the game away at the outset, the programme went on to relate the history of visceral learning, and did so very well. The phenomenon was introduced by way of examples (a young boy controlling the temperature of his hand, a gunshot victim regulating his blood pressure and Dr Miller himself wiggling one ear only), followed by a brief description of the relative impor-

tance of the somatic and autonomic nervous systems.

Dr Miller, we learned, first came to doubt classical theory on the independence of the autonomic system as a result of some very courageous experiments involving 16 human volunteers. When paralysed from the waist down by injections of curare or acetylcholine, these volunteers could still control their urine. If the bladder could be regulated in this way, he reasoned, might not other usually automatic functions of the body be controlled also?

For his experiments on rats, Dr Miller implanted electrodes into their brains so that he could reward them for a 'correct' response in blood pressure even when they were totally paralysed with curare. In living colour, the surgery involved must have turned off nearly as many sets as the recent party political broadcasts but to those of us inured to this kind of bloodshed it provided a fascinating insight into the procedure involved in this elegant experiment which, incidentally, took three years to develop. It was also good to see the ambiguities of the experimental work being admitted to the public and the importance of control experiments emphasised. In view of the *dénouement* to follow, this was just as well.

For the sombre truth about Dr Miller's experiments is that nobody has ever been able to verify them, although five years

and 2,000 unfortunate rats later another researcher, Dr Barry Dworkin, is still trying. Various reasons for his failure were presented to the viewer and then demolished, just as they were gaining credibility.

Had the company supplying the rats been rearing its charges in too much luxury and thus making them less susceptible to stress? No, when the animals were subjected to what Dr Dworkin called the "summer camp" treatment by dropping them in ice-cold water (heaven preserve me from American summer camps) they continued to turn in contradictory results. Could the curare used in the original experiments have been altered? Apparently not—but perhaps a placebo effect was taking place.

This sort of criticism in a television science programme is rare and could have been handled in a most destructive manner but the "Discovery" team should be congratulated on its balanced view of a most interesting topic.

The programme did contain a rather surprising flaw, however. Against a picture of a row of oriental mystics, seated deep in meditation and with electrodes taped to their shining heads, we were told of their amazing ability to confound modern science, represented by the scribbles of an electroencephalogram. No sooner seen than gone, the achievements of these people surely deserved more than this cursory mention.

matters arising

African swells, magmatism and plate tectonics

SIR,—Gill¹ states that the 'basin-and-swell' topography of Africa is now widely regarded as the product of heat flow anomalies in the upper mantle. Are these anomalies fixed with respect to the Earth's rotational axis or not? My contention is that they are not. The great Mesozoic to late Tertiary magmatic provinces of eastern Africa become progressively younger northward, when the overall movement of the African plate was in general northward and north eastward; and the mag-

matic provinces of west Africa have remained in more or less the same place since mid Jurassic times.

My ice-floe analogy⁴ was intended only to suggest that gentle lithospheric buckling might initiate the development of these broad thermal anomalies, or megaplumes, perhaps by enabling an asthenospheric up-current to develop, which would then be the source of magmatism and the main agent of crustal doming, and which could easily give rise to tensional features, such as rift valleys.

Gill quotes a figure of 10 km as the maximum possible wavelength for 'compressional warp structures', which seems improbable in a lithosphere 70–100 km

thick. I also question whether the idea that gentle warping in response to stresses arising from interplate 'jostling' is invalidated by reference to post-glacial isostatic recovery rates.

It is therefore still not impossible that a small degree of pressure-relief partial melting could trigger development of asthenospheric upcurrents. Gill is correct in inferring that I emphasise the mantle as a source of much salic magmatism, but whether such magmas are produced directly by partial melting or indirectly by high pressure fractionation is not important—what is important is that the mantle is demonstrably the source of some phonolites and trachytes. I still prefer the partial

melting model, and Gill states that such a model requires low temperature salic melts to be sweated off from the mantle earlier than basaltic liquids. In east Africa, great effusions of phonolitic magma were among the earliest manifestations of volcanism. In this connection, it is also worth noting that the difficulties of explaining the simultaneous availability of basic and salic magmas are just as great on a fractionation as on a partial melting model.

Yoder² has outlined a fractional melting mechanism to account for the contemporaneous occurrence of magmas of highly contrasted composition—in particular basalt and rhyolite, although there is no reason why similar arguments could not apply to alkaline basic and salic magmas. In a modified version of his earlier ideas, Bailey³ has proposed that plate tectonic processes could give rise to uneven stress distribution, resulting in gentle warping of continental plates. If low melting constituents were drawn into the arches, the resulting lower density mantle would provide a density contrast for continued uplift as observed in major continental alkaline provinces.

Finally, whether or not these comments constitute a valid reply to the points raised by Dr Gill, the central thesis of my paper is unaffected: alignments of individual magmatic centres within a magmatic province can only very rarely be attributed to movement of the lithosphere over a stationary mantle hot spot.

Yours faithfully,

Second Law of Thermodynamics

SIR,—In a recent article¹ Hillel proposes a statement of the Second Law of Thermodynamics which he claims is consistent with the time reversal symmetry of the microscopic laws of physics. Because the issues raised in this article nicely illustrate some of the fundamental misconceptions which continue to bedevil the subject of temporal asymmetry, I wish to make the following response.

In stating his form of the Second Law: "The entropy of a closed system tends to change monotonically with time", Hillel confuses the assumed underlying isotropy of time itself (ab-

sence of intrinsic preferred orientation) with the symmetry of physical processes with respect to time, a confusion which is in fact almost universal. The isotropy of time itself always enables us to replace the words "increasing entropy" by "decreasing entropy" in thermodynamic statements, for this merely amounts to an inversion of our conventions "later than; earlier than"—permitted provided these conventions are not referred to other physical processes (such as K^0 meson decay) which are asymmetric in time independently of thermodynamics. Hillel's remarks are thus a statement about time and not about thermodynamics.

Indeed, his is not a statement of the Second Law consistent with the symmetry of microscopic processes with respect to time, as alleged. For it is precisely the stated monotonic change of entropy in time which is the asymmetry of thermodynamics and which is apparently in conflict with the reversibility of atomic motion (Loschmidt's paradox). The fact that we are free to call the change an increase or decrease cannot alter the fact that the change is still asymmetric in time. Such a situation is well known to be incorrect, because it contradicts Poincaré's theorem, according to which all states in a closed system will be closely revisited eventually. Most laboratory systems soon reach equilibrium, after which fluctuations occur, during which the entropy both increases and decreases. These fluctuations often lead to observable effects such as Brownian motion.

A truly time symmetric statement of the Second Law, which is certainly necessary, has always been available:

If a closed system is in a random state of low entropy it is overwhelmingly likely to have been in a higher entropy state just before that moment and to be in a state of higher entropy just after that moment.

This statement resolves Loschmidt's paradox and is consistent with Poincaré's theorem. It also becomes consistent with our observations when it is appreciated that real systems are not permanently closed, but are branch systems from the main environment formed at a finite time in the past. Such systems are formed in low entropy states, and simply do not exist prior to their formation. Consequently, the monotonic entropy change referred to by Hillel is actually a consequence of the asymmetric formation of branch systems, which itself is related to the condition under which the universe emerged from the "big bang". It is actually possible to understand this condition in detail in terms of reaction thresholds of elementary particle processes on the one hand, and the

peculiarities of gravitational thermodynamics on the other. I refer the reader to my forthcoming book for a full discussion of these cosmological topics².

Yours faithfully,
P. C. W. DAVIES

King's College,
University of London

¹ Hillel, A. J., *Nature*, **242**, 456 (1973).

² Davies, P. C. W., *The Physics of Time Asymmetry* (S.U.P., in the press).

Dr Hillel replies: On the basis of classical dynamics, one can show that a system in a random state of low entropy is overwhelmingly likely to be in a higher entropy state just before that moment and also just after. This is put forward by Davies as a statement of the Second Law which has always been available in the literature. It is, however, a theoretical statement which is still commonly thought to be at odds with the observations which we summarise in the Second Law. This is precisely the basis of Loschmidt's paradox. The theory allows the possibility of a system "prepared" at a certain time, whose entropy was decreasing monotonically at earlier times. This seems to be inconsistent with observations and is forbidden by the usual statement of the Second Law. At this stage it is argued that in practice the system cannot exist before its preparation. I do not find this argument helpful. It does not remove the asymmetry but merely restates it. Is it possible, in principle, to observe such a monotonic decrease in entropy, and if so would the observations be physically acceptable to us? I argue that the answer is yes and that our statement of the second law should be modified accordingly. The statement I propose is consistent with the reversibility of the laws of mechanics (as embodied by Davies's theoretical statement). Poincaré's theorem is not relevant when considering statistical tendencies during times much shorter than the Poincaré time.

I do not accept Davies's distinction between the isotropy of time itself (absence of intrinsic preferred orientation) and the symmetry of physical processes with respect to time. A physical law is symmetrical under time reversal if, for any allowed sequence of events, the time reversed sequence is also allowed by the law. My proposed statement was designed to satisfy this criterion, because thermodynamic observations are symmetrical in this sense, and that is why a thermodynamic time reversal produces no observable effect other than an apparent inversion of our verbal conventions "later than; earlier than".

University of Manchester

obituary

G. Scatchard

GEORGE SCATCHARD was born in Oneonta, New York, on March 19, 1892, and died in Cambridge, Massachusetts, where he spent most of his life, on December 13, 1973. He received his AB degree from Amherst in 1913 and his PhD from Columbia in 1917. His PhD degree was in organic chemistry, on the synthesis and properties of quinazolines, but his interest shifted early to physical chemistry, and it is as a physical chemist, or, more precisely, as a thermodynamicist, that he established his reputation. He was Professor of Physical Chemistry at MIT for most of his career.

George Scatchard loved thermodynamics, its pure simplicity of expression, its certainty, its complete freedom from questionable assumptions. The vaguely understood effects of intermolecular interactions are always rigorously included in his equations as activity coefficients and their derivatives. Much of his theoretical work was concerned with the extraction of these non-ideal parameters from experimental data, with their interpretation, and with extrapolation methods that would eliminate them and permit exact determination of the simpler parameters, such as standard electrode potential and molecular weight, that enter into the definition of ideal thermodynamic behaviour. In the laboratory, George Scatchard dedicated himself to valiant efforts to match experimental precision to the precision of the equations he used for analysis. A characteristic of all his work, painfully discovered by many less patient experimenters who have sought to use his methods for analysis of their own data, is his ingenuity in devising plotting procedures that amplify experimental error and reveal at a glance the uncertainty of an extrapolation or in the drawing of a tangent.

George Scatchard was a severe critic. He did not necessarily expect others to match his own precision of thought or experiment, but he expected them to try their best. When he detected gross confusion or misconceptions, and especially when they masqueraded behind a facade of glib showmanship, he could be merciless. He will not be forgotten by anyone who presented seminars at the Harvard-MIT Physical Chemistry Colloquium when he was present. There was a perpetual frown on his face, deepening in intensity at each point where the speaker was glossing over

theoretical or experimental difficulties. At the end of the seminar there was relief when he asked an innocuous question, and (depending on the personality of the speaker) either anger or a silent resolve never to err again when he rose to expose a fallacy. There are undoubtedly some who remember George Scatchard with less than affection as the result of such an encounter, but there are many more who are grateful for his example and for the effect it had of raising their own standards of what is and what is not a valid piece of scientific research. As might be expected, George Scatchard's scientific papers often had the purpose of defining parameters and establishing methodology.

From 1930-40 he was mostly concerned with the thermodynamics of solutions, and especially of aqueous solutions of electrolytes beyond the range of applicability of limiting laws. During this period he developed the isopiestic method for evaluating osmotic and activity coefficient, and wrote definitive papers on the use of electromotive force and freezing point depression. He also wrote purely theoretical papers including a pioneering paper with John G. Kirkwood, during tenure of a Guggenheim Fellowship in Leipzig, on the electrostatic interactions of zwitterions.

During the Second World War, he divided his time between the Manhattan project of the AEC and the blood plasma fractionation project at Harvard directed by E. J. Cohn, who had been a fellow undergraduate at Amherst and was a life-long friend. The latter work led to a general interest in proteins and to his classic papers in 1946 on the state of equilibrium across a semipermeable membrane. These papers were written to provide a sound foundation for osmotic pressure measurements of protein solutions at finite concentrations, but of course apply quite generally to all thermodynamic properties of multi-component macromolecular solutions. Explicit extension to sedimentation equilibrium was made by Scatchard himself in 1954. The same basic theory provided the foundation for Scatchard's experimental work on the binding of ionic ligands to proteins and their interpretation in terms of specific binding sites and association constants, as well as for several papers on transport across semipermeable membranes.

There are very few scientists whose work one can legitimately compare with that of the handful of all-time great in-

tellects. Such a comparison can be made, without appearing presumptuous, between George Scatchard and J. Willard Gibbs. Nor is it derogatory to George Scatchard, in making this comparison, so say that Gibbs led the way and Scatchard followed for Scatchard himself said so. Few have the mental discipline that is required to go beyond a comprehension of what Gibbs accomplished, to an understanding of how he did it, to a sufficient insight into his thought process to be able to emulate it and to apply it to new and complex situations and George Scatchard was unique in his generation in his ability to do so. Without him many of the fruits of Gibbs' work would not have been gathered so soon.

C A Coulson

Just over a century ago, T. H. Huxley wrote a paper in which he described the liberally educated man as one "who has been so trained in his youth that his body is the ready servant of his will and does with ease and pleasure all the work that, as a mechanism, it is capable of: where intellect is a clear cold logic engine with all its parts of equal strength and in smooth working order . . . whose mind is stored with the great and fundamental truths of Nature . . . and who, no stunted ascetic is full of life and fire, but whose passions are trained to come to heel by a vigorous will, the servant of a tender conscience; who has learned to love all beauty, whether of Nature or of art, to hate all vileness and to respect others as himself". It is ironic that an atheist should have so adequately encompassed the life and style of Charles Coulson that, provided 'Christian' is substituted for 'tender' no better words could be found for his epitaph. This remarkable man was born in 1910 and died in Oxford on January 6, 1974, steadfast to the end in his adherence to his principles and beliefs and in his sense of duty to others so that his last concerns were not for himself but for those at home and in his department who were, in diverse ways, dependent on him.

He entered Trinity College, Cambridge, from his local Grammar School as an open scholar and duly and predictably collected his first in the Tripos examinations. His first paper in 1931 was essentially an attempted criticism of one of the redoubtable Harold Jeffreys' conclusions and its writing epi-

tomised his unfettered pursuit of truth even if it led him into conflict with higher authority. In due course he was elected a Research Fellow of Trinity sharing this distinction with two physicists also with Methodist connections, the late L. H. Gray FRS and D. E. Lea. Their scientific interests converged in the then embryonic study of the action of ionising radiation on living systems. Lea and Gray went on to make most distinguished contributions to this field, but Coulson's was not particularly outstanding and he turned to the newly emerged subject of theoretical chemistry, then broadly defined as the application of Wave Mechanics to molecular structure and bonding, which occupied him for the last 37 years of his life successively as lecturer in University College Dundee, ICI Fellow in the Physical Chemistry Laboratory at Oxford, Professor of Theoretical Physics at King's College London, Rouse Ball Professor of Mathematics at Oxford (for about 20 years) and finally as the foundation Professor of Theoretical Chemistry at Oxford.

A combination of enthusiasm, great industry, fluency and an uncanny judge-

ment of when to approximate made him a most prolific author (three books and over 300 papers). He touched on many chemical problems such as aromaticity, conjugation and hyperconjugation, charge distribution, shapes of molecules in ground and excited states. If his role initially was often to provide *post hoc* quantum-chemical justifications for many qualitative and semi-quantitative relations empirically perceived by chemists, he correctly foresaw that, once the computational obstacles had been overcome, the latent predictive powers of quantum chemistry would be realised and that it might outstrip instruments in quantitative precision.

Coulson will perhaps be remembered more as an unusually gifted teacher than a great researcher. He liked young people and they liked him—in their patois he 'related'. He had great sympathy for the intellectual difficulties of beginners and spared no pains in helping them. He loved lecturing and was a brilliant expositor, leaving his audience eager for more and confident that he could help them to an understanding which would enable them to select and solve prob-

lems. His summer schools in theoretical chemistry were world famous and a powerful influence in the dissemination of ideas and the development of the subject. They augmented the already strong attraction of Coulson's department for overseas visitors who often seemed to predominate in his research group.

Obituaries in *Nature* emphasise scientific achievement but it would be unjust to Coulson's memory not to recall that he was a deeply concerned Christian. This was manifested not only in his lay preaching to small congregations in insignificant Methodist Chapels or his public lectures to sophisticated audiences as in his Gifford lectures, but also in his willingness to play very active parts in organisations—such as a Vice-President of the Methodist Conference or as a working Chairman of Oxfam.

Honours were poured on Coulson but are not enumerated here for he would have preferred to be remembered simply as a practical idealist anxious to add to the sum of human happiness and understanding by advancing knowledge and by teaching and helping others, all of which he achieved abundantly.

Announcements

Appointments

J. Bardeen, H. B. G. Casimir, L. E. F. Neel, Sir Rudolf Peierls and Sir Alan Wilson have been elected Honorary Fellows of the Institute of Physics.

Sir Michael Perrin has been appointed a Trustee of the British Museum (Natural History).

Awards

The Council of the Institute of Physics has awarded the Guthrie Medal and Prize to R. L. Mossbauer of the Institut Max von Laue-Paul Langevin; the Rutherford Medal and Prize to A. E. Litherland of the University of Toronto; the Glazebrook Medal and Prize to B. J. Mason of the Meteorological Office; the Charles Vernon Boys Prize to P. G. H. Sanders of the University of Oxford; the Maxwell Medal and Prize to S. F. Edwards of the University of Cambridge and the Max Born Medal and Prize to W. Greiner of the University of Frankfurt.

The Councils of the French Physical Society and the Institute of Physics have awarded the 1974 Holweck Medals and Prizes to A. Hewish of the University of Cambridge and P. Nozieres of the Institut Max von Laue-Paul Langevin.

The Royal Society has awarded the first Herschel Medal to P. Wild of the CSIRO Division of Radiophysics.

Erratum

IN Fig. 1 of the article "Nitrosocarbaryl as a potent mutagen of environmental significance" by R. Elespuru W. Lijinsky and Jane K. Setlow (*Nature*, 247, 386; 1974), the vertical axis should have been labelled mutants/survivor. On line 17 of the figure legend 0.01M NC should read 0.01mM NC.

Corrigendum

In the article, "Mechanism of denaturation of haemoglobin by alkali" by M. F. Perutz (*Nature*, 247, 351; 1974) on page 343, paragraph 3, lines 9 and 10 of the section 'Probable mechanism' should read "Alkali denaturation of human oxyhaemoglobin has a negative entropy of activation . . ." and the first author of ref. 29 was misspelt and should be Air, G. M.

International meetings

April 8-10, 18th Annual Meeting of the Ecological Genetics Group (G. E. Marks, The John Innes Institute, Norwich, UK)

April 8-10, Course on Quantitative Microscopy for Materials Scientists (The Administrator, Royal Microscopical Society, Clarendon House, Cornmarket Street, Oxford OX1 3HA)

April 8-10, 8th Thin Films Conference (The Meetings Officer, The Institute of Physics, 47, Belgrave Square, London SW1X 80X)

April 8-11, The Engineering Uses of Coherent Optics (Mr E. R. Robertson, Department of Mechanics of Materials, University of Strathclyde, Glasgow)

April 8-12, International Symposium on Wound Healing (Secretariat International Symposium on Wound Healing, c/o Holland Organising Centre, 16, Lange Voorhout, The Hague, The Netherlands)

April 9, Society for Drug Research Symposium on Essential Hypertension (Dr A. B. Simmonds, Chelsea College, Manresa Road, London SW3)

April 9-10, Microstructure and Physical Properties of Non-metallic Materials (Dr D. Dew-Hughes, Department of Physics, University of Lancaster, Lancaster)

April 9-11, Gels and the Gelling Process (The Faraday Division, The Chemical Society, Burlington House, London W1V 0BN)

April 10, Applications of Remote Sensing—Data Processing and Analysis (R. W. Laing, Electro-Optics Division, Hawker Siddley Dynamics Ltd., Manor Road, Hatfield, Hertfordshire AL10 9LL)

April 15-16, 11th Annual Rocky Mountain Bioengineering Symposium (Clifford D. Ferris, The University of Wyoming, College of Engineering, Laramie, Wyoming 82070)

The French: are they legal?

It is ironic that at a time when Professor Jacques Monod has to go to extraordinary lengths to keep the Institut Pasteur alive, the French government should be spending several hundred million pounds annually on nuclear defence. The continuance of a vigorous and controversial French programme of atmospheric weapons testing is bound to stimulate more argument this summer both within France and beyond her borders and so the appearance of a summary by the Stockholm International Peace Research Institute (SIPRI) of the legal questions of French activities is a welcome event (*French Nuclear Tests in the Atmosphere: The Question of Legality*, SIPRI, Stockholm, March 1974).

France started her military nuclear programme in the 1950s and by 1960 was able to test fission devices in Algeria, at first in the atmosphere but from 1961 underground. In 1966 testing was moved to the South Pacific and has continued at the rate of several devices a year in the atmosphere since then.

Concerted attempts to stop atmospheric testing go back twenty years and it is undeniable that public opinion was a major factor in securing the signing of the Partial Test Ban Treaty in 1963 by all nuclear and potentially nuclear powers except France and China. Since then signatories have been restricted to underground testing. Protests against the French activities were relatively insignificant until about a year ago, largely no doubt because the French test site is remote from large centres of population.

It was last summer's series, announced in advance, which drew the sharp criticism, at both national and personal levels. As it turned out that the devices were modest but in expectation of megaton tests several countries raised objections, of which the most interesting and substantial were those of Australia and New Zealand who proceeded against France in the International Court of Justice.

The International Court was told that tests violated, among other things, the rights of Australian and New Zealand people to be free from radioactive fall-out and to have free passage on the high seas. It was asked to order the French to desist from testing. The French replied that the court was not competent since the matter was one of national defence and France had already declared such matters to be beyond the court's jurisdiction. The French government was not represented at the hearings and when the court concluded, by a vote of eight to six, that "the French government should avoid nuclear tests causing the deposit of radioactive fall out" France chose to ignore the order. The French government prepared a White Paper justifying its stance legally and scientifically in strong terms.

The danger with questions of national policy is that they are not easily broken down into neat compartments. Few actions can be at the same time politically acceptable, legal, moral and safe. Furthermore, how safe is safe? If the French action is dealt with on grounds of legality and harm to the environment, the outcome will be muddy. As it was, the court decision was by a vote of eight to six and French scientists could be found to match Australian scientists on the safety issue. Those who seek a clear resolution of this conflict by law or scientific discussion are pushing in the wrong direction. Nor is the French government on any firmer ground in saying that international hostility comes from a political desire to impede French defence policy and spite French independence. Many of the most vocal countries have little concern for French defence policy and many of those who do worry about it registered no protest. The issue at stake is not whether the possession of nuclear weapons is justified or sensible. It is, in the final analysis, whether firing nuclear explosions in the atmosphere is a civilised or moral thing to do in 1974.

It is very difficult to argue such an issue through reasoned debate. Nevertheless, it is possible for a national consensus to be reached and it is incumbent on governments which sense such a feeling to act appropriately. Labour in opposition expressed disapproval.

As for the French, the signs are that things are changing under increasing moral pressures. There are ample rumours that an underground test site is being developed at Mururoa atoll, maybe to be ready by 1975.

100 years ago

Note on apparently useless Colouring in the Flowers of a Fumitory (Fumaria capreolata var. pallidiflora, F. pallidiflora Jord.)

I observe that in this plant at Mentone the flowers attain their brightest colouring after the ovaries are set, and when fertilisation is no longer necessary, or indeed possible. During the period previous to impregnation, the flowers are pale and nearly white, and the pedicels erect or horizontal; afterwards they become pink, or even crimson, and the pedicels are recurved, and the colour of the petals, which retain their form and position until the ovary has nearly attained its full size, intensifies with the lapse of time.

If the reverse had been the case there is little doubt that we should have regarded the bright colouring as specially adapted to attract insects, and as existing for that purpose, insects being, according to Prof. F. Hildebrand,* important agents in the fertilisation of fumitories; but here, as the brighter flowers are those which no longer need or are capable of profiting by the interference of insects, this explanation ceases to be possible.

This little fact, therefore, would seem to be one which might be classed with those which teach us that, side by side with the developments and modifications which are plainly beneficial to the organism of which they form a part, there are others, which, as far as we can see, are neither useful nor harmful to their possessor, though they may, and frequently do, supply features which especially attract our attention and admiration.

J. TRAHERNE MOGGRIDGE

From *Nature*, 9, 423, April 2, 1874.

Cancer and leprosy in South Asia

Professor E. J. Ambrose, of the Chester Beatty Research Institute, London, describes in particular the work being carried out on leprosy and cancer in Bombay.

MOST of the major health problems in South Asia are due to infectious diseases into which research is highly advanced, and the control of the diseases has mainly become a public health problem. There are two exceptions to this—cancer and leprosy. Cancer is a disease which, with the increase in life expectancy, affects a progressively increasing proportion of the population. It is already the fourth ranking killer among the over-45s in Bombay. Cancer research is now an intensive worldwide activity but there are many unsolved problems; as they occur in South Asia these have a different emphasis from those of western countries, for example the disease may be very advanced before the patient reaches a specialist centre requiring more radical forms of treatment and therapy, and the patient may be more sensitive to drugs (because of dietary factors) than is usually the case in the West; also, cancers at certain sites (oral and pharyngeal cancer from chewing habits, for example) are more prevalent.

Tata Memorial Hospital

The Tata Memorial Hospital in Bombay has for many years been engaged in the specialised treatment of cancer, with patients from all parts of India and other countries coming for treatment. In 1956 a new research institute, the Indian Cancer Research Centre, was built under the guidance of Professor V. R. Khonolkar, its first Director. Following his retirement in 1963 the hospital and centre became amalgamated, under the Department of Atomic Energy, as the Tata Memorial Centre under the directorship of Dr J. C. Paymaster. Particularly important during this time were the developments in cancer epidemiology. Dr D. J. Jussawalla became director in 1973; he too is interested in this field.

Cancer

The Indian communities, with their extremely rigid marital customs, still provide a unique field for the study of cancer epidemiology, but intermarriage may destroy all these possibilities within the next 50 years. Carefully planned activities are now, or soon will be, in operation; already a study is in progress in a rural area (Colaba) and others are in prospect. The chewing of Pan with tobacco is a major factor in oral cancer, but chewing, smoking, the bidi and dietary factors also lead to a high incidence in the pharynx, oesophagus and upper intestinal tract generally. The most valuable information is likely to be obtained from comparative studies of Indian migrant populations who have acquired new habits, particularly in Africa. Breast cancer is also common in India and epidemiological studies of the incidence in Parsi (late marriages) and Hindu women (who have early marriages) show a higher incidence among Parsis.

These epidemiological studies are being backed by collateral studies in carcinogenesis at similar sites. Of particular interest have been the studies in breast cancer. An inbred strain of mice (ICRC strain) has been developed which shows a high incidence of breast cancer and of leukaemia. Interesting relationships between B and C particles and the role of hormones in cancer incidence have been worked out with these mice. Ultrastructure studies are proceeding in human breast cancer and in the investigation of common base sequences in B particles and in the nuclear DNA of breast cancer patients.

A second major research theme at the centre is immunobiology. Studies in oral cancer have already shown evidence

for cellular immune response, particularly in patients with oral tumours subjected to electrical cauterisation.

The third theme now being embarked on is combination therapy, with special reference to cancers common in India. Under Dr Jussawalla, important advances have been made at the Centre in treating patients with a combination of chemotherapy, radiotherapy and surgery for various types of cancer. The centre has potential for developing new drugs from extracts of Indian natural products. A screening programme for plant products based on National Institutes of Health procedures has been set up using P388 and L1210 mouse tumours. Several active plant products have been isolated. The value of such studies probably lies in adding to the repertoire of drugs available for combination therapy. Systematic experimental work is being carried out on the characterisation of relevant human tumours. These include drug assays by organ or monolayer culture, basic cytology and, in particular, cell surface studies. An important advance has been made in isolating from cobra venom pure proteins which are not neurotoxins but which combine with specific sites in the surfaces of cells including tumour cells. Such agents are likely to be of value in the cytodagnosis of human cancers. Of very topical interest is the work on nuclear magnetic resonance. This approach shows promise as a diagnostic aid based on the spin lattice relaxation time of cell water.

Leprosy

Leprosy is in some ways a more pressing problem in South Asia than cancer. The number of leprosy cases in these areas totals several million and is on the increase. Theoretically, leprosy could be prevented by an intensive public health programme but in practice it may be many years before these programmes lead to a reduction in the number of cases, particularly in view of the population explosion. Dapsone treatment is effective, particularly in early cases, but requires daily doses for 5–10 years or even a lifetime in lepromatous cases. Infection continues to spread in the population at large despite fine work by devoted workers engaged in the care of leprosy patients.

Professor Antia, at the Tata Department of Plastic Surgery, has for a number of years been engaged in plastic surgery of leprosy patients. This is extremely important for rehabilitation, leprosy being almost as much a social problem (with its stigma) as a medical problem. He has also built up with the support of industrialists training centres where leprosy patients can learn new crafts and engage in active work in small factories. But the total number of workers in the field is still small.

A team is being built up for various studies, including pathology of the most suitable sites for biopsy of leprosy patients, the investigation of the localisation of bacillae in nerve cells and their effects on nerve conduction velocity. Teams work on the cell biology of leprosy, including the intracellular culture of the organism, and on the use of the mouse footpad. Developments in the general field of microbiology and cell biology may well prove valuable in the future for leprosy. Techniques for the rapid assessment of the viability and growth of the bacillae may lead to a deeper understanding of the metabolic requirements of the organism and hence to systematic research in leprosy chemotherapy (for example DOPA itself might prove to be a specific metabolite for *Mycobacterium leprae* (Prabarkharan)) and the problem of treating intracellular bacillae as well as extra-cellular bacillae may now be investigated in living systems by autoradiographic methods so that the systematic study of human biopsy specimens is possible.

This account refers specifically to work in Bombay, with which I am familiar. In other parts of South Asia also, dedicated workers are actually engaged in the treatment of these two diseases and in research. The need is great because a large fraction of the world population lives in this region.

international news

The Pasteur Institute — independent but fading fast? Picture by Robin Laurance

AFTER nearly 90 years of unparalleled contributions to medical science, the Pasteur Institute in Paris is battling against a financial crisis and is in danger of closing. Set up with private money in 1888 for Pasteur to treat his rabies patients, the institute has remained stubbornly independent ever since. Over the years its researchers have won no less than eight Nobel prizes for medicine and have developed sera and vaccines for rabies, yellow fever, diphtheria, tetanus, tuberculosis and influenza. But despite this, and because of the escalating costs of research, the institute is running at a 15% deficit on its annual budget and observers say it could close down within five years.

The job of giving it a new lease of life falls largely on its director Jacques Monod, a musician turned biologist who decided there were "better chances for second rate biologists than for second rate orchestral conductors." But far from being second rate, Monod shared with two Pasteur colleagues a Nobel prize for medicine in 1965 for fundamental work on genetics; and in 1970 published *Chance and Necessity*, a philosophical treatise on the mechanics of inheritance, which was a best seller in France running second only to *Love Story*.

The headquarters of the institute in the Rue du Docteur Roux on Paris's Left Bank includes a 120-bed hospital for infectious diseases, a comprehensive science library and a total research staff of 1,150 including 300 postgraduate

Guiding the Pasteur through financial troubles

Robin Laurance, Paris

trainees. High specialisation is the keynote of the institute since it is orientated largely towards microbiology. Fifty laboratories provide facilities for basic and applied research into bacteriology, virology, physiopathology, immunology, molecular biology and other related studies.

Monod's office looks across to the original building where Pasteur lived and worked, and where doctors still treat rabies today in Pasteur's small book-lined consulting room. "One of our problems", says Monod, "is that we still live in the past. Members of the old institute fail to realise that we cannot maintain the position and style the institute enjoyed in the early part of the century."

One of the most severe financial handicaps has been the absence—until 10 years ago—of any patents on the institute's products. "If we had been collecting royalties all these years", says

Monod, "there would be no financial crisis." Now, Monod has to enforce the patent policy "even more ferociously." He has asked his colleagues not to publish a single word about new discoveries until a patent has been applied for. And it is a rule that non-commercially-minded scientists find hard to accept.

But even with royalties and licence fees, the institute's income was still not going to match its research needs. So last year Monod formed the production and sales side into a high powered commercially orientated organisation called Institut Pasteur Production (IPP) with all the shares held by the Pasteur Foundation. Monod became President and he spent nine months finding the right men to run it for him. He brought in Nestlé's head of home marketing as Vice-president and Michelin's sales chief to run the marketing division.

Monod is bitterly opposed to any suggestion of a government takeover and even less willing to see the institute absorbed into the university system. And he insists that he is ethically justified in enjoying the freedom from state or capitalist control. "Of course no French government could afford to watch the institute disappear because it carries such prestige—it's a national emblem. But if it did have to step in it would appoint the executive and effectively take control. Everything would get bogged down with typical French bureaucracy—the plague of this country of ours—and Pasteur would lose a great deal. And the universities are so badly

run, it would be even worse to come under their control." Monod has no hesitation in saying he would resign on the spot in the event of either fate.

A fund-raising campaign last year raised £2 million, and IPP's first year showed promising results with sales totalling £8 million, due largely to a new 'flu vaccine which looks like being more effective than anything else on the market. Two million shots have been sold since last October but it is still not available in the United Kingdom or in the United States as it has yet to satisfy the drug control authorities.

"I think the authorities have gone too far", says Monod. "The thalidomide disaster has made them overcautious and companies bigger than our own IPP are facing closure because the exhaustive trials are simply costing them too much. When I'm in a good mood, I think of the whole thing as a kind of sport. Maybe the odds at 2:1 in favour, and that makes it a game worth playing."

The institute's latest discovery, about to undergo clinical tests, is a vaccine which will give the body increased resistance to all bacterial and viral diseases. If proved successful it could be the discovery of the decade. But with IPP's distributor in the United Kingdom forced to offer it at such low prices for vaccines to compete favourably on the British market, it too may never be used in Britain.

"It is a mistake", points out Monod, "to believe that we have come to the end of vaccine discovery." He says that whooping cough vaccine is still far from satisfactory and that vaccines against viral hepatitis and against gonorrhoea are urgently needed. And it is these fields, and in immunology as a whole, that Monod believes the institute's researchers can, given the chance, make vital contributions. "But there's no doubt", he warns, "that there is still a very serious danger of the institute closing. If IPP is given time to grow—and we must treble the present sales—then we'll be all right. It all depends on how long that takes."

AEC case for fast breeders

Colin Norman, Washington

IN June last year, the US Court of Appeals in Washington dealt a potentially severe blow to the United States fast breeder reactor programme—the great white hope for meeting the country's energy needs by the end of this century. The court ordered the US Atomic Energy Commission (AEC) to obey the laws of the land by publishing a comprehensive analysis of the combined environmental effects of several hundred breeder reactors scattered throughout the United States. The AEC has now produced a massive draft report which predictably argues that the reactor will be environmentally acceptable, safe and desperately needed.

The report, which runs to some 2,000 pages, is now doing the rounds of other government agencies, public interest groups and environmentalist organisations, and it will be the subject of a public hearing on April 24. Not surprisingly, it is generating a good deal of heat in the long and bitter battle between the Atomic Energy Commission and its critics over the safety and acceptability of nuclear power.

The objective of the court suit, which was brought by the Scientists' Institute for Public Information, was to force public discussion of the dangers and environmental consequences of the entire commercial breeder reactor programme, before development had progressed so far that it would be difficult to halt. The critics reckoned that if the huge scale of the proposed programme, together with the dangers inherent in fuel processing and waste disposal, could be brought into the public spotlight, the case against the breeder would be compelling.

But the AEC, helped by the energy crisis in general and by the Arab oil boycott in particular, has turned the argument about the size of the programme around and thrown it back in

the faces of its critics. The agency argues, in short, that the breeder reactor will offset United States dependence on imported fuel, that it provides the surest and most acceptable means of meeting the predicted demand for energy in the 1990s and beyond, and that to abandon breeder reactor development now could put the United States in the position of relying on foreign breeder technology at some time in the future.

First, the scale of the programme. The AEC's report indicates that if all goes according to plan, the first commercial breeder reactor will start operating in 1987 and by the year 2000, 400 individual plants, each capable of producing 1,000 MW of electricity will be at work in the United States. They would be producing between them as much electricity as the entire United States electric power industry generated last year. By the year 2020, as much as 2.2 million MW could be generated by fast breeder reactors.

The AEC argues that some other means of providing that energy must be found if the breeder reactor programme is halted and that there is nothing on the horizon which is either capable of filling the gap or technologically proven. To which the critics reply that if the money to be spent on breeder reactors were put into other energy systems, such as solar power and geothermal energy, then they could be developed to the point where they would be capable of meeting energy demands. The AEC replies that if it turns out that the concepts, promising as they are, cannot be turned into energy in time, the United States would find itself in an energy crunch by the end of this century.

What particularly worries opponents of the breeder reactor is the amount of plutonium which will be produced by a string of reactors operating around the country. The advantage of the breeder over conventional nuclear power plants is that it can be fueled on nonfissionable uranium which cannot be used in the so-called first generation reactors. The uranium is converted during the reactor operation into plutonium, which can

Dounreay — Britain's first fast breeder station, on line without objections

then be used to fuel the reactor on another operating cycle—in other words, the reactor breeds its own fuel.

The advantage is that the breeder reactor does not require additional uranium to be mined, which is fortunate because uranium reserves in the United States are estimated to last for only another 25–30 years. But the problem is that plutonium is highly toxic, its radioactivity decays extremely slowly and it can be turned relatively easily into the heart of a crude atomic weapon. Opponents of the breeder programme have therefore concentrated their attacks on the health and national security hazards of plutonium. Clearly, the larger the commercial breeder programme, the more plutonium will be produced, and the greater the perceived hazards.

The AEC analysis states, however, that strict safeguards are enforced at all facilities which handle plutonium, to prevent any of it from falling into the hands of people looking for a nuclear weapon. Unfortunately, however, a study conducted last year by the General Accounting Office (GAO) concluded that the safeguards at some installations would scarcely deter an amateur burglar, let alone a well planned theft. Although the AEC maintains that it has stepped up its safeguards in the light of the GAO's findings, the public relations aspects of the matter are difficult to overcome.

As for the health risks, the AEC's draft report concludes that the entire breeder reactor programme is likely to cause less than 2.2 cancer deaths in the United States over the whole lifetime of the reactors, fuel fabrication plants and waste disposal facilities. But that conclusion was challenged even before it appeared in print by two nuclear energy specialists working for an environmental organisation called the Natural Resources Defense Council and it is likely to develop into a bitter wrangle.

The two critics of the AEC's analysis, Dr Arthur Tamplin, an ex-AEC employee and long a thorn in the agency's flesh, and Dr Thomas Cochran, have challenged the basis of the nuclear industry's estimates of the potential damage caused to the lungs by particles of plutonium. They have argued, in short, that it is unrealistic to base safety standards on the likely dose of radioactivity to the entire lung from tiny particles of plutonium. A single particle is likely to give a dose of radioactivity to the whole lung of about 0.003 rem per year but Tamplin and Cochran argue that the tissue immediately surrounding a particle of plutonium will get a dose of radioactivity as high as 4,000 rem per year. Therefore, they argue, the AEC should reduce the amount of plutonium allowed

to be released into the atmosphere by a factor of 115,000.

Those two points—the potential for diverting plutonium into the hands of somebody capable of producing a crude bomb and the health risks from plutonium released into the atmosphere—are thus likely to form the centrepiece of the public hearings next month. But environmental causes have been taking a battering in the past few months in the United States, as public attention has swung away from the environmental crisis to the more obvious effects of the energy crisis, and the AEC can be expected to play the breeder reactor's promise of supplying 2.2 million MW of electricity for all it's worth.

It is, perhaps, worth noting that earlier this month, the British 250 MW Prototype Fast Reactor at Dounreay became critical, and the fast breeder reactor programme is proceeding in Britain relatively unencumbered by requirements for public discussion of risks and benefits.

Nuclear inquiry

WITHIN weeks of the Dounreay Prototype Reactor going critical, and while the choice of Britain's next nuclear reactor system hangs in the balance, the Royal Commission on Environmental Pollution has announced its decision to investigate standards of nuclear safety in the country. The Commission on Environmental Pollution is a standing commission, recently reconstituted under the chairmanship of Sir Brian Flowers, and the choice of subject for its first inquiry is thought to have been decided by the long term implications of a switch from conventional to nuclear power generation rather than by the immediate crisis of consciences over hardware selection.

Sir Brian has taken pains to point out that members of the commission "do not feel able to involve themselves in highly technical questions of reactor design in relation to safety, or with comparisons between one type of reactor and another". Nevertheless, in the next breath he added that in the general grounds of concern about environmental hazards "in a choice between reactor systems great and perhaps overriding weight should be given at the present time to the issue of safety". The commission will also examine the problems of radioactive waste disposal and the transport and storage of nuclear materials, particularly plutonium.

Business report

Roger Woodham

ALBRIGHT and Wilson, the chemical company, has had to reduce the book value of this ill-fated phosphorus plant at Long Harbour, Newfoundland, because of continuing production difficulties. In 1973 the plant, designed to produce 72,000 tons of phosphorus a year, only had an output of 40,000 tons, which, at that, was an improvement on the situation in 1971 and 1972.

The Long Harbour plant is one of only four of its size in the world—it consumes 140 MW of electricity—and Albright and Wilson admitted in 1971 that the two manufacturers using a comparable electrode arrangement in the furnace had experienced and overcome similar difficulties—broken electrodes. Nonetheless these problems, which have necessitated several major shutdowns, do not seem to have been sorted out at Long Harbour and the company is throwing in at least part of the towel by revaluing the plant from £19.9 million to £11.2 million.

In spite of these upsets Albright and Wilson managed to notch up an increase in profits from £2.75 million to £7.47 million, just short of its 1964 best of £7.57 million.

With prices of raw materials as they are, however, the company's future fortunes are going to depend on how one of its major customers, the farmer, reacts to the prospect of higher phosphate prices.

● The prices in Britain of scientific instruments are by no means all susceptible to the ravages of inflation, although the cost of an instrument that pushes a technique to the limit possible at a given time does jump ahead in leaps and bounds.

Instrument price trends

	Routine	Research
NMR	£10,000 (£10,000)	£40,000 (£80,000+)
IR	£1,410 (£1,420)	£8,000 (£20,000)
UV	£700 (£750)	£5,000 (£8,000)
GC	£600 (£1,000)	£2,000 (£3,000)

Broadly speaking, the prices of routine instruments that have the same capabilities as their counterparts ten years ago, say, have marked time and in real terms have fallen. The reason is that companies have made use of new technology to simplify and cheapen the manufacturing process. With really high performance equipment, on the other hand, the manufacturer is involved in much larger development costs and is much more sensitive to the effects of wage inflation. Top notch instruments

are thus much more expensive now than they were ten years ago, a situation which is often described in terms of a 'sophistication factor'. In the case of imported instruments, which account for a greater proportion of the research type than the routine type in Britain, the customer also, of course, has to contend with price changes introduced by fluctuating exchange rates.

The table shows the state of affairs for nuclear magnetic resonance (NMR), infrared (IR) and ultraviolet (UV) spectroscopy and for gas chromatography (GC). The prices in brackets are the prices today and the others are the prices ten years ago.

Oil on troubled waters

A SYMPOSIUM on hydrocarbons in the marine environment has been postponed by the Ministry of Agriculture because they do not think the meeting is necessary. The organisers, the Torry Research Institute and the Marine Research Station at Aberdeen, planned to discuss the effects of oil pollution at Aberdeen in May. About 100 scientists said they would attend, but they are now being told that the symposium has been postponed. Apparently, somebody who should have been asked wasn't. The Ministry of Agriculture's Administrative Officer, Mr W. R. Small, explained that the symposium is not necessary because there are "six or seven" other symposia going on which deal with the same, or allied, subjects. "This should never have been mooted in the first place without the right people being asked",

he thought. "There is simply no unanimity about the urgency of the symposium at this stage. There is a limited corpus of scientists scurrying around these meetings, and at this moment the ministry cannot afford to have its resources spent unnecessarily. You know, it's like a Beau Geste fort, with the same men appearing at different battlements all the time."

A corollary to this spirited assessment of the marine biologist's round is that the men who appear at the battlements on home ground tend to include a fair proportion of junior scientists who are actually engaged in research in the field. The overseas junkets are sometimes made up of more senior men who count foreign travel among their hobbies. The Aberdeen cancellation note points out that the symposium would have clashed with a similar meeting in Maryland—a conjunction which might have caused a crisis of conscience among the senior men, but would not have presented a problem to the junior workers who would have been glad of the chance to talk about pollution problems on their own doorsteps.

Furthermore, Aberdeen is not doing at all badly for profits from services related to the offshore oil industry at the moment and some people would not really be interested to hear about hydrocarbon pollution if oil ran ankle deep in the streets. The Scottish press is keen to pick on stories involving damage to the environment and would almost certainly have been looking for pickings at the Aberdeen symposium. There was a chance that the benefactions of the oil industry would be called into question. This has now been avoided.

More planning problems at Loch Carron

THE public inquiry into setting up deep-sea oil platform construction sites at Drumbuie, Loch Carron on the west coast of Scotland opened again on March 18 after being adjourned for several weeks, but was immediately adjourned again at the request of the National Trust for Scotland, the main objector. The trust was opposed to an entirely unexpected environmental report being placed as evidence.

The trust owns the land on which the platforms will be built if the Drumbuie site is approved for development. They were objecting to a surprise environmental report commissioned by the Scottish Development Department from Sphere Environment Consultants of London. This report considered several other possible sites in the area. None of the objectors had been told that the report was in preparation and their counsel successfully moved for an adjournment until April 1.

The National Trust and the other ob-

jectors had finished giving their evidence against the development when the inquiry was adjourned in February, and this new development will considerably prolong matters. The environmental report and an expected consulting engineer's report, commissioned by the Department of Energy, both come out in favour of Drumbuie as opposed to other sites in the area but give alternatives if the National Trust land does not become available. As the proposed bill to nationalise land needed for oil platform construction is not going ahead under the new Labour government, a special bill in Parliament will be needed to use the trust's land.

Sphere suggested a site on the Isle of Skye near Broadford Bay as their second choice. On the other hand the consulting engineer's report gives a site on Loch Kishorn, near Carron, as the second choice and Broadford Bay as the third.

Australian science news

Peter Pockley, Sydney

IN a speech to the Science and Industry Forum of the Australian Academy of Science in February, Dr Moss Cass, the Minister for the Environment and Conservation, announced the formation of a new Bureau of Environmental Studies within his department. In doing so, Dr Cass has rejected alternative proposals for establishing a statutory institute, or for strengthening the existing responsibility for some environmental research within the Commonwealth Scientific and Industrial Research Organisation (CSIRO), which in any case comes under the Minister for Science, thus revealing the old problem of duplication where departments overlap.

The Bureau of Environmental Studies will have three main areas of responsibility. First, it will survey, assess and integrate existing studies done by other groups. Second, it will develop programmes to fill identifiable gaps. A third group in the bureau will try its hand at environmental 'futurology', with the aim of anticipating the problems of 20 to 30 years ahead. Here we see the strong strand of anti-industrial growth and humanism in Dr Cass's philosophy, for this group will be charged with developing some kind of human progress index. For this, Dr Cass suggests the term 'gross domestic welfare', which he hopes could be derived from a combination of measures of environmental quality, social indicators and productive capacity in both goods and services. Recruitment for the bureau's staff will start shortly. It looks as though they will need to be in the market for social philosophers as much as ecologists.

● In a further move indicating the diplomatic initiatives between the Australian Labor government and the communist world, the first exchange of visits between Australian and Chinese scientists was announced recently. A party of nine Australians started an 18-day visit to Canton, Peking, Shanghai and other centres on March 18. The party of four representatives of the Australian Academy of Science, four from the Australian National University (ANU), and one Asian scholar as interpreter will be led jointly by Professor Sir Rutherford Robertson, President of the Academy, and Dr R. M. Williams, Vice-Chancellor of ANU. The inclusion of an interpreter chosen by Australia is seen as a significant advantage for the party; he is Professor Liu Ts-un-yan, Head of the Department of Chinese at the ANU.

The scientific interests of the Australians include astronomy, spectroscopy, plant physiology, genetics, mathematical

In Britain the Family Planning Association (FPA) has taken over the production of a comic about birth control methods, called *Too Great a Risk*, which was the brainchild of the FPA's South-west London branch. The headquarters of the FPA took control of production and distribution because the comic proved so successful on a local level: since its launch in March last year 70,000 copies of *Too Great a Risk* have been supplied to school and college teachers, youth

statistics, classical thermodynamics, nature conservation, biomedical sciences and civil navigational aids. The party will officially be guests of the Academia Sinica, who will sponsor a return visit of Chinese scientists to Australia later in the year.

● Only a few hours before rushing back to Britain to preside over the general election, Queen Elizabeth performed her first major constitutional function in her newly designated role as 'Queen of Australia'. This was the formal opening of the 28th Federal Parliament in Canberra. Despite the governing Labor leaders' avowed preference for a republic in Australia in due time, this occasion was marked by as much ceremony and circumstance as in the Queen's speech at the opening of Parliament on February 28 revealed, in tersely abbreviated terms, a massive programme of legislation which Prime Minister Whitlam's government hopes to push through in its second year in

office. (Some of it will truly require much hoping and pushing because the government faces a hostile opposition in the Senate where the opposition parties hold a firm majority—a Senate election due in the middle of this year is unlikely to change the balance of power in this upper house.)

Science *per se* rated a mere six words, namely "A science council is being planned". This passing mention con-firmed how tentative are the current plans of the Minister for Science, Mr Bill Morrison, for replacing the former Advisory Committee for Science and Technology which he axed a year ago. Mr Morrison has said that legislative action is needed to establish the proposed Australian Science Council on a proper footing but hopes are now dim-pling that his portfolio has enough political pull to get some priority for science affairs on the legislative list. It now looks unlikely that a Science Coun-cil could be formed before next year, the last scheduled year of Labor's

three-year term.

Previous speculation that Mr Morris-son would be promoted out of the science portfolio is now dead. He has shed all but residual responsibility for Papua New Guinea affairs and there is a fair flow of publicity over the min-ister's name, relating mostly to admin-istrative changes within the minister's responsibility. But the politics of science in Australia are rating no mention at all from the news journalists, the com-mentators and, worse, from the politi-cians themselves.

● Postscript to our news (Nature, 247, 500, 1974) of the appointment of Pro-fessor E. Joseph Wampler as Director of the Anglo-Australian Telescope. His salary has now been disclosed as \$A23,000. This is \$A3,850 more than that of the new Director of the Austra-lian Institute of Marine Science (which is the equivalent to the salary of a full professor) and is within the range of salaries paid to Chiefs of CSIRO Divisions.

correspondence

Academics in Chile

SIR,—The international scientific community must be aware of the dramatic condition of the Chilean academic community. The military authorities who have taken over the power in all Chilean universities issued new rules stipulating that:

"Any nomination or contract must from now on be considered strictly provisional. The Special Commission [installed by the military rector] will propose renewals or cancellations of such contracts in each particular case.

All students must apply for reinscription . . . The Special Commission will decide on the opportunity of accepting or refusing such applications.

Any professor, administrative employee, technician or student suspected by civil or military courts will be immediately suspended . . . Any one of them being sentenced will be dismissed; students will be permanently expelled from the Universities.

The same action will be taken towards those having answered citations from the courts . . ."

This quotation is taken from an official statement issued by the new authorities in charge of one Chilean university on September 28, 1973. Analogous decisions have been made in all universities, including the Universidad Catolica de Chile. As a consequence of this, many professors or academic staff have lost their jobs. In the most favourable cases (such as that of professors on official leave or absence abroad), scientists "have been granted permission to present their resignation" (usually with retroactive effect). Many have been arrested, on an arbitrary charge or no charge at all, usually after anonymous denunciations of neighbours or colleagues. Many of them are still in prison and an official International Lawyer's Commission has presented evidence for many cases of physical torture. In La Serena, professors against whom no special charge could be found have been executed in spite of having been condemned to minor sentences (less than two months of imprisonment).

Several other members of the academic community have been executed without being permitted to present their defence.

In various universities, departments like geography, sociology, economics and biophysics have been completely dismantled.

These facts must be publicised and

scientists all over the world should press governments and international organisations in order to prevent further repressive actions. In addition, there is an urgent need for help to academic people who already could, or will eventually be able to, leave the country. We have on record many excellent applications in all fields ranging from mathematics to social sciences.

All those able to offer laboratory space and positions, even on a temporary basis, should contact the Committee of Assistance to Chilean Scientists (CACS), by writing to M. Imbert, Collège de France, 75231 Paris-Cedex 5.

Yours faithfully,

North Sea oil

SIR,—Although I agree with the opening paragraph of Eleanor Lawrence's article on the planning aspects of North Sea oil (*Nature*, 247, 416; 1974) I feel that the remainder of the article leaves much to be disputed.

What does Mrs Lawrence mean by 'getting the oil ashore as quickly as possible'? If she means seeing the oil flow as soon as possible then there is probably nobody against it. Already, nine platforms are in various stages of construction for the Auk, Beryl, Brent and Forties fields, and at least one or two other fields will be exploited using drilling rigs rather than production platforms. There is, therefore, no block to how quickly the first oil will come ashore. If, however, she means by 'the most extreme preservationists' those who are opposing the intended maximum rate of exploitation of this important resource (as is current policy) then she is referring to no splinter group of cranks. It includes Liberals, Scottish Nationalists and a good number of Socialists who have all committed themselves against seeing oil used in this way.

It is, I would agree, right to criticise present planning procedures because

they treat each separate proposal in isolation rather than in the context of a coordinated plan. This is plainly ridiculous. The advantage that the present system offers, however, is time to reflect. The technological situation in relation to oil extraction from the sea bed is changing so rapidly that there are real dangers that what seems essential today will be of historic interest in a couple of years' time. Thus although the Condeep gravity concrete structure is currently in favour (and if to be built in Britain, probably needs to be constructed at Loch Carron) this ignores the alternative deep-water platform designs already being offered by different companies at existing yards, ignores the recent innovations in 'floating' platforms announced recently and ignores the technology for seabed completions which it is expected will be erected for deep water cases within the next two years. It would be a tragedy if rushed decisions caused the destruction of a way of life at Loch Carron, especially if it were for only a short term return.

The real iniquity of the present system is that the objectors should be involved in costs of many thousands of pounds. This is not because of the law itself but because of government choice. Section 267, subsections 7 and 8 of the Town and Country Planning (Scotland) Act 1972 states clearly that costs may be awarded to the objectors but the Secretary of State for Scotland has consistently refused to consider doing this. Thus, although objectors must pay their costs from their earned and taxed incomes, development companies can offset their costs against profits before tax. At Dunnet Bay the objectors were faced with a bill of £3,000 while Chicago Bridge decided to go elsewhere. At Loch Broom, the Action Group incurred costs in setting up its case against the proposed development at Ullapool before Mowlem discovered that the site was unsuitable anyway. Meanwhile the taxpayer contributed to an environmental impact survey that was never needed. The main objectors at Drumbuie will be faced with bills of tens of thousands of pounds. There is a very clear case indeed, in the light of the special circumstances that oil developments present, for the proposing companies to be held responsible for costs of genuinely concerned objectors.

news and views

Genetic factors in hepatitis

ALTHOUGH much has been written about the possible mechanisms leading to the establishment of the chronic carrier state of hepatitis B antigen and the remarkable geographical variation in the prevalence of such carriers, which may number in some areas many hundreds of thousands, the genetic hypothesis promulgated by Blumberg and associates (*Proc. natn. Acad. Sci. U.S.A.*, **62**, 1108; 1969) remains a contentious issue among students of viral hepatitis.

Examples of inherited susceptibility to infection have been described in several animal species including man and it is recognised, of course, that many other factors in the environment such as sex, age at exposure, state of nutrition, immunological factors, socio-economic circumstances and so on also affect susceptibility and resistance to infection. The discovery of hepatitis B antigen resulted from the interest of Blumberg and associates in inherited polymorphisms. Family studies carried out in the islands of Cebu and Bougainville in the Pacific, and on a more limited scale elsewhere, seemed to be consistent with the hypothesis that a gene designated *Au¹* is responsible for persistence of hepatitis B antigen once infection with hepatitis B virus has occurred. This gene is considered to be common in tropical areas but rare in temperate zones. Individuals homozygous for this gene (phenotype *Au¹/Au¹*) would have persistent antigen without overt manifestation of hepatitis, although they may remain as carriers of the associated infectious agent, whereas the heterozygotes (phenotype *Au¹/Au*) and individuals without the gene (*Au⁰/Au⁰*) would not remain as carriers. Persistence of hepatitis B antigen in certain other diseases such as leukaemia, lepromatous leprosy and Down's syndrome (mongolism) is believed to be of a different nature, namely an inherited susceptibility to infection not only with hepatitis B but with the agents responsible for these other diseases (Blumberg, *Ann. N.Y. Acad. Sci.*, **197**, 152; 1972). This would explain the association of the antigen with other diseases in circumstances in which the individuals with the susceptibility gene were exposed to hepatitis B virus; and absence of the association when exposure did not occur.

Ceppellini and colleagues (Convegno Farmitalia, *Antigene Australia ed Epatite Virale*, Minerva Medica, Torino, 53; 1970) also studied the segregation of the postulated trait for persistence of hepatitis B antigen among 165 families in Sardinia. A similar conclusion on the presence of an autosomal recessive locus was reached, although with some distinct qualifications. First, there was a sharp decline in the carrier rate of the antigen after the age of 20, an observation which has also been reported from many other high prevalence areas. Second, all of the reported matings, excepting one family, were between parents where only one parent was antigen-positive or where both parents were negative. In the family in which the antigen was detected in both parents, only two of the seven children were also positive. This finding on its own would rule out a simple hypothesis of recessive inheritance with complete penetrance of the homozygous recessive genotype. Ceppellini considered this fact, but decided to disregard the critical mating.

Now Vyas has reported (*Nature*, **248**, 159; 1974) a second critical mating which also fails to support the postulated inherited susceptibility to persistence of hepatitis B antigen. A pedigree with antigen-carrying parents and their progeny of three children were tested for hepatitis B antigen and hepatitis B antibody by several methods including the most sensitive techniques currently available—radioimmunoassay and passive haemagglutination. The antigen was not found by repeated testing of the serum of the three children. Hepatitis B antibody was, however, detected in the serum of the eldest son, aged 10 years, and so provides unequivocal evidence of past exposure to the antigen resulting in a normal immune response to infection. This is crucial evidence against susceptibility to the chronic carrier state inherited as a simple autosomal recessive trait.

Lederberg (*Hepatitis and Blood Transfusion*, edit. by Vyas, Perkins and Schmid, Grune and Stratton, New York, 89; 1972) previously summarised the position by stressing the alternative hypothesis to the genetic factor—that familial clustering may be entirely a function of an increased opportunity for environmental exposure to the virus. Furthermore, it stands to reason that if a parent is excreting the virus this will augment the chance that any of the offspring may acquire it, particularly if the mother is the transmitter.

Another aspect of the genetic basis of susceptibility to hepatitis is implicit in the finding that the frequency of certain genetic markers on the heavy chains of immunoglobulin G (Gm types) was always greater in multiply-transfused Italian patients with thalassaemia who were persistent carriers of hepatitis B antigen than in those with hepatitis B antibody (Blumberg and associates, *Nature*, **236**, 28; 1972). With respect to Gm types, individuals who are heterozygous for Gm factors are less likely to encounter Gm types different from their own and are therefore less likely to develop anti-Gm. Such persons when infected with hepatitis B virus, which incorporates certain host components in its protein coat, would be likely to develop persistent antigenaemia and minimal liver damage. On the other hand, individuals who are homozygous for Gm types (that is, they have fewer Gm types) are more likely to encounter Gm types different from their own and thus develop antibodies to them. Such persons, when infected with hepatitis B virus, would be more likely to have an acute infection and an increased probability of developing hepatitis B antibody. Schanfield and colleagues (*Nature new Biol.*, **243**, 81; 1973) examined for Gm allotypic markers samples from blood donors submitted routinely for testing for hepatitis B antigen in San Francisco and Minneapolis. The frequency of the various Gm phenotypes did not vary significantly among the Caucasian donors investigated according to the presence or absence of hepatitis B antigen or its antibody. Similarly, there was no significant excess of anti-Gm among individuals with hepatitis B antibody when compared with those with persistent hepatitis B antigenaemia. These findings are not in accord, at least in a normal adult population, with the hypothesis of a direct association between the polymorphisms of the Gm types and hepatitis B antigen.

It does not follow, of course, that the hypothesis of a genetic predisposition to hepatitis did not have a productive impact, since it did generate much discussion and considerable experimentation.

A. J. Z.

Blue-green algae as model organisms

SOME filamentous blue-green algae show a one-dimensional pattern of differentiated cells. In *Anabaena* and *Nostoc*, heterocysts arise from vegetative cells. Heterocysts are relatively large, rounded, refractile cells, which are believed to fix nitrogen. The transformation from vegetative cells to heterocysts by way of the intermediate proheterocysts can be stimulated by transferring algal filaments to a medium free of fixed nitrogen. The conditions required vary among the species; for example, in *N. muscorum* and *A. cylindrica* there is not a well-defined pattern of proheterocysts in a medium containing fixed nitrogen, although there may be in *A. catenula*.

Two separate problems have recently been addressed in the literature: first, how the pattern of heterocysts is controlled; and, second, what the function of heterocysts is and whether this can be correlated with the appearance of specific proteins during heterocyst differentiation.

Mitchison and Wilcox (*Nature*, **239**, 110-11; 1972) found that vegetative cells in *A. catenula* divide with a mean time of 14 h. The best defined event in the cycle is the formation of a septum between daughter cells which takes 1-2 h. The divisions are always asymmetric and follow a simple rule which had no exceptions in the 600 cases observed. If a cell arises as, say, the left daughter of a division then its left daughter is always the smaller. Furthermore, heterocysts (which do not divide) only develop from the small daughter cells, which themselves grow more slowly than the large daughters although both attain the same size before their next division. This provides a very simple example of determination following a cell lineage rule, as if the vegetative cells were behaving as a set of stem cells. Mitchison and Wilcox, however, say that they know of no other example in which this recursive rule is followed.

The spacing of heterocysts, although it depends partially on cell lineage, is finally determined by other factors, as most small daughter cells do not develop into heterocysts. Wilcox, Mitchison and Smith have examined these in detail (*J. Cell Sci.*, **12**, 707-723 and **13**, 637-649; 1973). In the first paper they define the pattern and make a model of the spacing mechanism; in the second they test the model experimentally, and report on the ultrastructural aspects of heterocyst differentiation.

In both species of *Anabaena* used the pattern of heterocysts is quite regular: in *A. cylindrica* there are 9.3 ± 2.8 vegetative cells between heterocysts (or preheterocysts) and in *A. catenula* there are 10.1 ± 2.5 . The simplest model to account for this was put forward by Fogg, who suggested that heterocysts produce a diffusible metabolite which inhibits further heterocyst differentiation. That is, there is a threshold concentration of inhibitor below which small daughter cells will differentiate into heterocysts. Wilcox *et al.*, however, feel that this model is too simple as they found that early differentiation towards heterocysts is reversible implying that there might be a competitive interaction as well.

In particular, the authors examined heterocysts that arose in the terminal intervals of filaments. In central intervals proheterocysts tend to appear exactly at their centre, but in the terminal intervals proheterocysts, and thus heterocysts, are displaced towards the end of the interval. On the simple threshold model one would expect to see heterocysts at the ends of terminal intervals, where inhibitor concentration would presumably be lowest. Wilcox *et al.* suggest instead, however, that an end behaves as though it were one half of a hypothetical interval consisting of the original terminal interval joined to its mirror image. That is, the end wall of the terminal cells acts as a reflecting barrier to inhibitor diffusion.

A terminal heterocyst would thus be equivalent to one half of an adjacent heterocyst pair, which almost never occurs. The addition of a competitive interaction to the simple threshold model could then account for the rarity of terminal heterocysts.

Wilcox *et al.* therefore made artificial ends by breaking *A. catenula* filaments in intervals where central heterocysts would normally be expected to arise. As expected, the developing heterocyst was displaced towards the break, producing a normal end interval within 8-12 h, a time too short for differential division to be important. They then, in *A. cylindrica*, made mirror-image heterocysts by breaking a cell close to a proheterocyst. As expected this led to regression of the proheterocysts, with a probability depending on the number of cells left intact between it and the break, although there are relatively few regressions when the cell next to a proheterocyst is broken. This may be because the proheterocyst forms a normal, permeable cell junction on the break side which could allow a leakage of inhibitor.

A further piece of evidence for compensation is that groups of proheterocysts may appear in *A. catenula*. All but in a group one regress, unless there are more than three cells in the group, when one heterocyst may differentiate at either end.

Wilcox *et al.* propose that even after a proheterocyst has begun to produce inhibitor it remains susceptible to its effects. When a threshold, which increases with developmental age, is exceeded, the cell regresses. The contribution of heterocysts to inhibitor production sum, so one can inhibit another. The most important feature, the competition, implies also that a heterocyst can inhibit its own development, as in regression after filament breakage.

In their second paper Wilcox *et al.* give further support to their model by investigating the conditions in which a heterocyst can inhibit itself. They used *A. catenula* and made filament fragments containing heterocysts at all stages of development with no, one, two or three neighbouring cells on each side. Regression frequency decreased both with developmental age and with number of neighbours. Moreover, heterocysts at the end of a fragment had a lower probability of regressing than heterocysts with a neighbour on each side, probably because inhibitor can leak through the heterocyst wall.

The competitive interaction which is enhanced by NH_4^+ can apparently be broken down by 7-azatryptophan (Mitchison and Wilcox, *Nature new Biol.*, **246**, 229-233; 1973). When it is added to the growth medium, at a concentration of $5 \times 10^{-6}\text{M}$ or greater, the spacing between heterocysts is reduced and multiple heterocysts may form. Alteration of the pattern begins within 10 h and is independent of concentration, although the final pattern is not. All the changes observed correspond to an increase of inhibitor level in their model, although there is no evidence to link the effect of 7-azatryptophan with any aspect of metabolism.

Fleming and Haselkorn (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 2727-2731; 1973) separated heterocysts from vegetative cells, in *Nostoc muscorum*, by treatment of the filaments with lysozyme and then centrifugation. They found that the increase of nitrogenase activity, which occurs on transfer of filaments to a medium free of fixed nitrogen, parallels the increase of number of heterocysts formed, and that heterocysts synthesise many proteins not found in vegetative cells. Furthermore, they were able to isolate (on SDS gels) three proteins which bore a strong resemblance to the structural proteins of bacterial nitrogenase the induction of which was also related to the increase in nitrogenase activity.

The authors speculate that heterocyst differentiation begins when the concentration of NH_4^+ falls below a threshold and that products of nitrogen fixation in heterocysts repress the development of, and nitrogenase synthesis in, neighbouring vegetative cells. As the ability to inhibit

further heterocyst development is acquired before pro-heterocysts can fix nitrogen, the authors suggest that pro-heterocysts might be able to transport NH_4^+ to their neighbours. They also point out that heterocysts must become refractory to repression as they continue to synthesise the structural proteins of nitrogenase while fixing nitrogen. Although there are many ways in which induction and repression might be mediated, it is interesting that both groups working on this problem have been forced to models with very similar qualitative features.

The blue-green algae proved a very simple system for the study of patterned differentiation. It should be possible not only to discover the mechanism for the control of differentiation, but also to correlate differentiation with events at the molecular level, a normally elusive ideal for developmental biologists. *Anabaena* and *Nostoc* thus join *Hydra* and *Dictyostelium discoideum* as model organisms in which the outlines of a developmental control system are known, and which are simple enough that the details of differentiation during pattern formation can be followed.

From a Correspondent

A Chinese view of tectonics

PROFESSOR J. S. LEE was a Chinese earth scientist highly regarded both in China and the West, so the appearance of a long posthumous article by him entitled "Crustal Structure and Crustal Movement" in *Scientia Sinica* (16, 519-559; 1973) is an event of great interest. The paper was written in 1970, and so cannot claim to be an ideal representation of present-day Chinese thinking on the subject, but it is nevertheless a most fascinating insight into Chinese approaches to tectonics; the more so because Lee's conclusions, based primarily on Chinese evidence, are simultaneously near to and far from Western views.

In a subject as explosively developing as the earth sciences, it is desirable to know how much of the literature of other than Chinese origin the author has consulted. It is clear even in this reference-free paper that Professor Lee had access to nothing beyond about 1963. The magnetic stripes off western North America are described in some detail, but what they imply "is not yet clearly known" beyond that basic or ultrabasic rocks are present. Mid-ocean ridge magnetic anomalies are not mentioned. Seismicity only receives the briefest qualitative attention. With this crippling lack of the ingredients that went into plate tectonics (and without the 1961 seafloor spreading hypothesis), Lee's synthesis is bound to be incomplete. He further complains that "reactionary imperialistic blocs" in scrambling for the wealth of the sea floor and other purposes have not published most of their data. Nevertheless his paper has much interest.

He first looks at the various hypotheses of crustal movement. Some geologists—most of the "traditionalist Americans and some orthodox geotectonicists in the Soviet Union" (Belousov, no doubt)—insist that vertical movement is dominant and flatly deny the importance of horizontal movement. This he sees as founded in ideas of continental fixation and thus "metaphysical, and utterly dogmatic. This guiding thought was propagated to our land and has brought considerable loss to our geological cause". Lee then goes on to consider possible aspects of crustal movement—cooling and contraction, tides, expansion, convection currents (not ruled out but a "purely metaphysical hypothesis"), isostatic compensation, continental drift and what is called "China's own road". Most of these are dismissed peremptorily, but continental drift (separate from convection currents) is considered briefly as "not entirely unreasonable". Lee, however, cares little for palaeomagnetism and does not accept field reversals.

China's "own road" is an approach which he, as author of a textbook on the geology of China, finds most appealing: learn what you can from China's "extremely superior conditions of structural development". Extensive field work is necessary on structural theories—as Chairman Mao has it, "Man's knowledge is verified only when he achieves the anticipated results": advice perhaps more suited to debugging computer programs than scientific research. Once Lee discovered certain broad scale structural regularities in China, he was prepared to extend them to the rest of the Earth. These features are:

- A latitudinal system of E-W zones revealed by both topography and aeromagnetics. One is at 40° to 42°N and is seen to extend through Central Asia, Turkey, the Mediterranean, under the Atlantic, intersecting the Appalachians, producing an east-west gravity anomaly in the western United States and running into the Mendocino fracture zone. Other world circling zones at 32°-34°N and 25°N are described and one or two in southern latitudes.

- A meridional system is identified by north-south trends, less obvious in China but strong elsewhere such as in the Urals and East Africa.

- The Neocathaysian system striking NNE-SSW is a feature of importance on the oceanic margins of Asia.

- The Cathaysian (NE-SW) system is again an Asiatic feature.

- Shear structural systems are complex but all reflect areas in which there has been shear in the horizontal plane.

Lee observes that surface features are often not in complete agreement with those at greater depth, "in other words they are detached from each other". Furthermore the upper part of continents is inconsistent with the ocean floor and so he is led to consider the importance of horizontal movement. But of what? Earthquakes in Yunnan and Kweichow are about 10 km deep so it seems that there is a gliding of the upper crust over the lower. North and South America have glided westward from Europe and Africa leaving the Atlantic exposed. In the Pacific it is the ocean floor which is moving westward and the inclined plane of earthquakes beneath Japan and the Kuriles is a manifestation of shearing between the old Pacific and the underside of Asia. Many other instances are given of meridional and latitudinal displacements of the Earth's crust, leading respectively to movement from higher to lower latitudes and to splitting of continents.

What is the driving force? Lee sees forces from the Earth's rotation as the only ones able to produce the two orthogonal types of motion. The resolved tangential component of centrifugal force is seen as the source of movement towards the equator, presumably (though this is not stated) in the form of *Polfluchtkraft*, the force on floating bodies that so occupied German geodynamicists in the 1920s. Westward movement is seen, on the other hand, as the result of variations in the rate of rotation of the Earth.

Very little of all this will move Western geophysicists, utterly committed to plate tectonics, to turn with enthusiasm to the Chinese literature. Lee's view of the world, so heavily dominated by what he saw in the field in China, is reminiscent of other qualitative syntheses that were made in the 1960s, all of which are now forgotten. And yet there is much to learn from this paper. Lee had to develop his ideas in the context of continental tectonics, a field which is still open to much discussion. The paper shows the fierce independence of the Chinese from the influence of the Russian school whose insistence on the dominance of vertical movement in the crust effectively kept the Soviet Union from participating in the excitement of the past ten years. It further shows that although Lee's views were by no means those of the West, there are grounds for discussion with Chinese earth scientists. Students brought up on Lee's interpretations would not find it difficult to understand, if not to accept, plate tectonics.

Markers in heterogeneous nuclear RNA

from our
Molecular Genetics Correspondent

ONE difficulty in following the production of messenger RNA from its putative precursor, heterogeneous nuclear RNA (HnRNA), is the lack of markers which can be traced from the nuclear molecules to those in the cytoplasm. Such markers are needed both in the part of the HnRNA which is conserved and becomes the messenger and also in the part which is degraded. The importance of such sequences is emphasised by the use which they have been in tracing the path of production of ribosomal RNA from its large nucleolar precursor, where methyl groups identify the ribosomal RNA sequences and certain oligonucleotides have been found which may be part of the degraded sequences.

The marker usually taken to identify the mRNA sequence in HnRNA is the 200-long sequence of poly(A) which is added to the 3' end of the molecule before production of mRNA. The experiments which have shown that preventing addition of this poly(A) prevents production of mRNA suggest that it plays some part essential for messenger maturation. But these experiments have relied on drugs which block this process and in such cases it is always possible to argue that some unanticipated side effect of the drug is really responsible for its effect. The experiments now reported by Nakazoto, Edmonds and Kopp (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 200; 1974) therefore achieve two purposes. By identifying short oligonucleotide sequences of adenylic acid within HnRNA, they identify markers in it additional to the poly(U) sequences previously identified by Darnell and his colleagues; by comparing the metabolism of this oligo(A) with that of the 3' terminal poly(A), they confirm that the distinctive metabolism of the terminal poly(A) is indeed due to its position and not to some unexpected property of the drugs used to inhibit its addition.

Two drugs commonly used to follow the metabolism of HnRNA and mRNA are actinomycin and 3'deoxyadenosine (otherwise known as cordycepin). Low doses of actinomycin suppresses synthesis of rRNA but not HnRNA; higher doses inhibit both rRNA and HnRNA synthesis. Cordycepin does not inhibit synthesis of HnRNA, but by preventing the addition of poly(A) to the precursor, also seems to prevent production of mRNA, a strong line of evidence supporting the idea that HnRNA and mRNA have a precursor-product relationship. The oligo(A) recovered from within the HnRNA molecule

seems to be some 20-40 residues long, compared with the 200 bases of the terminal poly(A). Their metabolism is quite different. High levels of actinomycin which inhibit HnRNA synthesis prevent the synthesis of oligo(A); but have no effect on the addition to previously synthesised HnRNA of the terminal poly(A). Cordycepin has the opposite effect; it has no effect upon the synthesis of the internal oligo(A) but is effective in preventing addition of the terminal poly(A). By comparing these two sequences, these experiments provide strong support for the idea that the terminal poly(A) is indeed added by a mechanism quite distinct from that responsible for synthesis of HnRNA and that its addition is essential for the cleavage from HnRNA of mRNA and its transport to the cytoplasm.

The oligo(A) does not appear in cytoplasmic mRNA and so provides a marker for the sequences of HnRNA which are ultimately degraded in the nucleus. Because these experiments compared internal and terminal poly(A) sequences, they provide information only about the HnRNA molecules which contain terminal poly(A); Nakazoto *et al.* remark that this proportion represents some 15-40% of the total nuclear population. In the largest HnRNA molecules containing external poly(A), Nakazoto *et al.* calculate that there is on average less than one small internal sequence of oligo(A) per molecule. Although present in many of the HnRNA molecules, it is not therefore an inevitable feature. A more detailed examination of its occurrence and location will be necessary.

Miniaturised insect retina

from our Insect Physiology Correspondent

THE more closely the compound eyes of insects are studied, the greater becomes the respect which they inspire. Formerly regarded as primitive and inefficient structures, they are now revealing unsuspected complexities. Some of the latest acquisitions in this field are reviewed and new ones described by Snyder, Menzel and Laughlin (*J. comp. Physiol.*, **87**, 99; 1974) who deal with the functional specialisations of the 'fused rhabdoms' of the insect eye. In most of the photoreceptors of vertebrates and invertebrates the photosensitive pigment resides within the receptor cell in a column of higher refractive index than the surrounding medium. This column of photopigment acts as a dielectric waveguide which confines the light within the photoreceptor, where it is absorbed by the photopigment and transduced to receptor potential.

Structure of a typical cylindrical ommatidium with a fused rhabdom in the honey bee. *a*, General structure showing: C, corneal lens; CC, crystalline cone; R, retinula cells; N, nucleus; Rh, fused rhabdom; A, axons. *b*, Structure as seen with electron microscope: the fused rhabdom at the centre consists of sectors with parallel microvilli—the rhabdomeres of the eight retinula cells. *c*, A segment of the fused rhabdom showing the microvilli of two adjacent retinula cells. The microvilli of each rhabdomere are parallel in a hexagonal lattice.

Thus in vertebrate eyes, with few exceptions, each rod or cone is an independent waveguide, optically isolated from its neighbours. But in most compound eyes of insects several photoreceptors are fused together to form a centrally located common light guide, the rhabdom. In the worker honey bee (see figure), for example, eight photoreceptors (the retinula cells) each contribute a wedge of microvilli (termed a rhabdomere) and these eight wedges are fused together to form the common rhabdom. The parallel microvilli carry the photopigment aligned on the microvillus membrane so that each rhabdomere is sensitive to the plane of polarisation of the incident light. There is increasing evidence that the fused rhabdom is formed by rhabdomeres with different spectral absorptive powers, so that, given the necessary neural connections, spectral discrimination is possible in a single ommatidium. This will make possible a fine-grain colour vision, permitting hue discrimination in a very small field of vision.

But there are more subtle properties of the fused rhabdom which the authors have brought to light. The retinula cells of one cylindrical unit, or ommatidium, can interact both electrically and optically. Electrical coupling between cells occurs, and when this takes place between cells with microvilli aligned in different directions, it will impair the sensitivity to polarised light. On the other hand, if coupling occurs between cells with different photopigments, this

will result in a broadening of the spectral sensitivity curves of each and may be responsible for the double peaked spectral sensitivity curves that have been obtained from single retinula cells.

Optical coupling can take two forms. In some compound eyes, such as those of dragonflies and some Diptera, the rhabdoms are tiered and there is a direct filtering of light through successive photoreceptors with different properties. But even when the rhabdomeres are fused in a single column, since this acts as a single light guide, the absorptive properties of each rhabdomere will influence the light as it passes down the column. Indeed each rhabdomere acts as if it were an absorptive filter in front of all the others: the rhabdomeres function as lateral absorption filters. As a result the shape of the spectral sensitivity curve is more or less independent of the amount of light absorbed: the flattening of curves by self-absorption is prevented by optical coupling. This means that, as a consequence of optical coupling, each retinula cell can have a high absolute sensitivity while preserving its narrow spectral sensitivity curve.

In this way arthropod photoreceptors have solved the problem of collecting the small amount of light available to them and have increased the efficiency of quantum capture without loss of spectral sensitivity. Moreover, unlike electrical coupling, optical coupling within the ommatidium confers these benefits without loss of sensitivity to the plane of polarisation of the incident light. In many forms it looks as though polarisation sensitivity has been a by-product of rhabdom structure without much functional significance. Where a high level of polarisation sensitivity exists, it is found to be the result of a specialised arrangement of rhabdoms to give maximum sensitivity independent of spectral discrimination—as in the ninth retina cell of the honey bee, or the eighth cell in the fly.

In vertebrates the same problem of combining high absolute sensitivity with well defined spectral discrimination has been solved by having a dual system of rods and cones for low intensity and high intensity vision respectively. But it seems that certain deep sea fishes have also developed a system comparable with that of insects in which optical coupling provides a visual system which combines high spatial acuity, absolute sensitivity and colour discrimination in a compact array of photoreceptors behind a dioptric apparatus of extremely low aperture. So far as the insect is concerned, the ommatidium cannot be considered as a loose collection of receptors sharing the same dioptric apparatus; it must be seen as a highly integrated unit with remarkable discriminatory powers.

Carcinogenicity and mutagenicity

from a Correspondent

A WORKSHOP meeting convened by the International Agency for Research on Cancer and the Catholic University of Louvain was held in Brussels on December 10-12 to discuss approaches to assess the significance of experimental chemical carcinogenesis data for man. The meeting was chaired by Dr P. N. Magee (Middlesex Hospital Medical School, London) and the topics included comparative metabolism of chemical carcinogens, chemical carcinogenesis *in vitro* and mutagenicity tests.

Comparative metabolism

A. H. Conney (Hoffman-La Roche, Nutley) discussed the marked species differences in metabolism of foreign chemicals and their importance in determining the outcome of exposure of animals or man to chemical carcinogens. He emphasised the great difficulties and dangers involved in studying the metabolism of carcinogens in humans and the possible value of metabolic studies on non-carcinogenic chemicals. Recent work on metabolism of chemical carcinogens *in vitro* has included the use of biopsy or postmortem samples of human liver and preparations of human placenta, leukocytes or foreskin. E. Arrhenius (University of Stockholm) described how chemical carcinogens are metabolised, usually by microsomal enzyme systems which might activate or inactivate them. N-oxygenation was claimed to activate and C-oxygenation to inactivate aromatic amines, the reactions differing in their dependence on cytochrome P_{450} and in their response to inhibitors such as methylmercury compounds. The active metabolites, usually of electrophilic character, react with components of the cell nucleus and endoplasmic reticulum.

The evidence that N-nitrosamines are activated by enzymes to form alkylating agents whereas N-nitrosamides can form similar products in the body without enzymes was mentioned by R. Montesana (International Agency for Research on Cancer, Lyon). The organotropic action of the nitrosamines may be determined by the distribution of the activating enzymes but metabolism, although necessary, is not a sufficient condition for carcinogenesis. Human liver preparations metabolise dimethylnitrosamine *in vitro* at a comparable rate to rat liver and show a similar pattern of nucleic acid methylation. F. J. Wiebel (National Cancer Institute, Bethesda) described metabolic pathways of polycyclic hydrocarbons which lead to less or more carcinogenically-active products. Epoxides may be the active

metabolites with dihydrodiols, phenols and quinones as less active products. The enzymes concerned are present, and can be induced, in mouse skin and are inhibited by 7,8-benzoflavone which also inhibits skin carcinogenesis. Inhibitory effects of actinomycin D and cycloheximide suggest a role of messenger RNA in the induction of the enzyme. Differences in the activities of aryl hydrocarbon hydroxylase in human leukocytes may provide a basis for predicting susceptibility to these carcinogens in man.

P. L. Grover (Institute of Cancer Research, London) discussed the significance of polycyclic hydrocarbons in tobacco smoke for the induction of human lung cancer, suggesting the possible production of somatic mutations by enzymatically-formed epoxides. Direct evidence, including *in vitro* studies with human lung microsomes, and indirect evidence for formation of epoxides was presented and the importance of their further metabolism by hydrolases and glutathione conjugation was discussed. E. Huberman (Weizmann Institute, Rehovot) described a highly sensitive cell-mediated assay for mutagenesis in mammalian cells in which mutation to 8-azaguanine resistance was scored in V79 Chinese hamster cells, growing on layers of lethally irradiated cells which still retained the capacity to metabolise chemical carcinogens. Increased mutation rates, inhibited by 7,8-benzoflavone, were obtained with benzpyrene and methylcholanthrene. N-methyl-N'-nitro-N-nitrosoguanidine was active without the irradiated cell layer. Mutagenic activity correlated with carcinogenicity. P. T. Iype (Paterson Laboratories, Manchester) described methods for the *in vitro* culture of liver parenchymal cells with characteristic morphological, biochemical and immunological properties including contact inhibition, the presence of desmosomes, glycogen, ligandin, tyrosine aminotransferase and the capacity to produce serum albumin. Transformation was obtained with methylnitrosourea and other chemical carcinogens and confirmed by transplantation.

Testing for carcinogenesis

In vitro models for carcinogenesis testing were discussed by J. A. DiPaolo (National Cancer Institute, Bethesda) who emphasised quantitative experiments using mammalian cells and the production of cancer by transplantation of transformed cells into animals as the end point. Syrian hamster fibroblasts growing on irradiated rat cells were transformed by polycyclic hydrocarbons and the results correlate with carcinogenic potency *in vivo*. Toxicity reactions and transformation were separate and distinct processes. A similar banding pattern was observed in the chromo-

some of transformed cells and tumour cells but these were considered secondary rather than causal. Pretreatment of the fibroblasts by irradiation or with methyl methanesulphonate enhanced the effect of some chemical carcinogens. Some compounds, including nitrosamines, were negative in the *in vitro* system but gave positive results if the embryos from which the fibroblasts were derived were exposed to the carcinogens transplacentally. The replica plating technique of Lederberg has been applied by T. Kuroki (University of Tokyo) to the selection of ultraviolet sensitive clones from mouse cell lines and of mutants induced in BHK-21 cells exposed to N-methyl-N'-nitro-N-nitrosoguanidine.

Testing for mutagenesis

Possible damage to the genetic material of man and animals from exposure to pesticides in the environment was pointed out by R. Fahrig (Zentral-laboratorium für Mutagenitätsprüfung, Freiburg), who described a range of tests for mutagenicity of such environmental chemicals with emphasis on the reasons for negative results. These included insensitivity of the system used, lack of activation of the compound and failure of penetration of the compound to the critical sites in the cells. Little is known about long-term exposure of animals to mutagens. The known liver microsomal activating systems for chemical mutagens were surveyed by N. Loprieno (Institute of Genetics, Pisa) whose group has used forward mutation and mitotic gene conversion and recombination with *Saccharomyces* as the test organism. The mutagenic activity of ethyl methane-sulphonate, a direct alkylating agent, is enhanced by mouse liver microsomes, but this effect was not explained. T. Sugimura (National Cancer Center Research Institute, Tokyo) summarised current work on AF₂, a nitrofurant derivative used for about 7 years as a food additive in Japan. This compound gave positive results for DNA damage in repair tests and was positively mutagenic in *Escherichia coli* although negative in the *S. typhimurium* mutants of Ames. Carcinogenicity testing has so far proved negative and the compound was inactive in the sebaceous gland inhibition test in mouse skin. The great difficulties in extrapolating these results to man were discussed.

The positive correlation between the mutagenicity of selected chemical carcinogens in *Neurospora crassa* and their carcinogenicity in laboratory animals was emphasised by F. J. de Serres (National Institute of Environmental Health Sciences, Bethesda). He described a system of specific locus mutations in *Neurospora* which showed that chemical carcinogens produce

mainly base-pair substitution mutations, by contrast with the conclusions of some other workers that many potent carcinogens induce frame-shift mutations. He concluded that it may eventually be possible to develop a battery of tests that will permit the reliable prediction of carcinogenicity and mutagenicity. Finally, G. Röhrborn (University of Heidelberg) reviewed the mutation theory of cancer, emphasising that most human cancers do not show a definite mode of inheritance, though chromosomal aberrations are seen in human tumours (for example, Bloom's Syndrome) and carcinogens of various kinds interact with DNA. Rats treated with N-nitrosomorpholine or N-butyl nitrosourea showed evidence of chromosomal damage in the bone marrow and work is in progress to develop tests for carcinogenicity and mutagenicity in the same species of animal.

Superconductivity of metastable alloy films

from our Materials Science Correspondent

In the early fifties, Buckel and Hilsch in Göttingen deposited mixtures of metals such as bismuth and tin by evaporation on to substrates cooled by liquid helium, and so made supersaturated alloy films some of which showed superconducting behaviour to unexpectedly high temperatures. The method has been designated vapour quenching. This work has in recent years stimulated a fluctuating follow-up, first at IBM and now at Bell Telephone Laboratories, research which has gone in parallel with the growing amount of research on alloys cooled ultrarapidly from the melt. Both vapour-quenched and melt-quenched alloys are apt to be supersaturated, sometimes grossly so, and are thus in metastable form. Uncovenanted phases, not indicated by the phase diagram, are also apt to be formed.

The group at Bell Telephone have now published a detailed account of their recent researches on the superconductivity of vapour-deposited films (Testardi, Wernick, Royer, Bacon and Storm, *J. appl. Phys.*, **45**, 446; 1974). One novel feature here was that the substrate was not cold, but on the contrary held above room temperature during deposition. Instead of evaporation, the comparatively new method of getter-sputtering was used, in which the vapour species are generated by bombardment of metal targets by argon ions, in an atmosphere cleaned by gettering. The alloys, mostly high-melting compositions with superconducting major constituents, were found to produce metastable phases, as evidenced by X-ray diffraction. Com-

bination such as Hf/Nb, Mo/Nb/Re, Re/W, Rh/Zr were examined.

The superconducting transition temperatures, T_c , are plotted as a function of deposition (that is, substrate) temperature, and the generalisation emerges that T_c peaks for deposition temperatures which are close to phase-transformation temperatures in the equilibrium diagrams. The alloys studied mostly have equilibrium phases of δ , α -Mn or similar structural type near the temperatures which led to the highest values of T_c . The investigators conclude that structural instability enhances the superconducting transition; presumably, the phase which is in process of being formed is one which, in its normal state, is especially favourable for superconduction. But Testardi *et al.* were generally not able to identify with certainty what phases, metastable or otherwise, were in fact present in their films; they did establish that some X-ray lines at least corresponded to abnormal structures. This work shows that getter-sputtering is an effective technique for forming alloy phases with unusual properties, and that this virtue of the technique is by no means restricted to experiments with cold substrates.

At first sight, deposition of these alloys on a heated substrate is entirely distinct from deposition of bismuth or copper alloys on substrates held at 4 K. In fact, the difference is only apparent. Testardi's alloys are so refractory that even at temperatures around 400–600°C, diffusion in the bulk is very sluggish. Where the alloys have phase transitions in this temperature range, the new phases form very slowly when the alloy is cooled from the melt, whereas formation from the vapour permits the newly arriving, momentarily mobile atoms to form themselves readily into the equilibrium phase or a metastable transition phase of related structure. (It seems that the metastable structures form most readily in the immediate vicinity of a temperature at which a phase change would take place according to the phase diagram.) What Testardi and his colleagues have introduced is a form of vapour-quenching at elevated temperatures in which the film is transiently in a labile, adaptable state and is therefore at once frozen into instability.

Two of the alloys investigated, Mo₃Ru₃ and Ru₂W₃, also show exceptional hardness and corrosion resistance (Testardi *et al.*, *Met. Trans.*, **4**, 2195–2198; 1973) which might make such alloy films interesting for use as thin-film resistors, optical mirrors, razor blade coatings and so on. Since these alloys have now also been shown to have useful superconducting characteristics, they may also prove of value for use in superconducting memory devices.

Where does a membrane end?

from a Correspondent

THERE is currently a considerable amount of effort being expended in attempts to define the molecular structure of the surface membranes of cells. Unfortunately, there is no adequate definition of a 'membrane protein' and workers in this field compromise, either explicitly or, more often, implicitly, by adopting operational definitions. Singer and Nicholson (*Science*, **175**, 720; 1972) distinguish between 'integral' and 'peripheral' membrane proteins largely on the basis of their ease of solubilisation from membranes. This is, of necessity, an arbitrary decision: an integral membrane protein is one which remains attached to the fragmented vesicles which usually comprise 'purified membranes'. The problem with this approach is illustrated by the following comparison. A large fraction of the total cellular sialic acid is accessible to trypsin and therefore presumably is at the surface; however, membranes purified by some of the most commonly used procedures (Warren *et al.*, in *Specificity of Cell Surfaces*, edit. by Davis and Warren, 1967) contain only a small fraction of the total sialic acid. Does one conclude that the sialylated molecules are peripheral membrane proteins, or extracellular material, or alternatively, that the membrane preparation is inadequate? Clearly, it boils down to a semantic argument avoided only by operational definitions.

There is also the opposite problem of association, artefactual or otherwise, of non-membrane proteins, for example serum proteins, with cells and membrane preparations. One could propose, as a definition of a true membrane protein, that it be synthesised by the cell itself and possess a hydrophobic region inserted into the lipid bilayer. This definition also has a number of disadvantages; not least that it is, in practice, difficult to determine whether a particular protein is rooted in the lipid bilayer. It would also exclude proteins synthesised elsewhere and inserted into the membrane of a cell. There is clear precedent for such an export-import system in the case of egg yolk proteins which are synthesised in the liver.

Two recent papers illustrate the problem. Peterson, Rask and Lindblom (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 35; 1974) report that HL-A antigens released from 'crude spleen cell membranes' by papain digestion contain the protein β_2 -microglobulin, previously described as a protein present in serum and urine. Peterson *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **69**, 1697; 1972) had earlier found that this protein can be

detected immunologically on the surface of human leukocytes. Now they prove that β_2 -microglobulin is associated with several different HL-A antigenic specificities throughout papain treatment, a variety of column chromatographic procedures and immunoprecipitation by HL-A antisera. The β_2 -microglobulin was identified by electrophoretic mobility, antigenicity and tryptic peptide mapping. The HL-A specificities resided in polypeptides of about 33,000 daltons but, in each case studied, were associated with a polypeptide of 11,800 daltons indistinguishable from β_2 -microglobulin. The β_2 -microglobulin did not itself carry HL-A specificities. Does this association represent artefactual binding arising after digestion, or does it pre-exist on the intact cell and what is the origin of the β_2 -microglobulin? No evidence is presented as to whether the β_2 -microglobulin is synthesised by the spleen cells themselves. Previous workers, who have described a polypeptide of similar molecular weight in purified HL-A, found that it was synthesised by the cultured lymphocytes from which it was isolated (Cresswell, Turner and Strominger, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 1603; 1973).

In an unrelated study Ruoslahti, Vaheri, Kuusela and Linder (*Biochim. biophys. Acta*, **322**, 352; 1973) discovered that an antigenic activity found on the surfaces of cultured chicken embryo fibroblasts is present in chicken serum. In this case the serum protein is of high molecular weight and migrates as an α -globulin. Antisera specific for this antigen were obtained by the unlikely procedure of treating intact fibroblasts with insolubilised papain and injecting the digest (after removal of the enzyme) into rabbits. Surprisingly, a monospecific serum was obtained. Using this serum, Ruoslahti *et al.* were able to show that the antigen is present on the surfaces of the fibroblasts (but not of several other cell types) and is synthesised by them (incorporation of 35 S-methionine). The fibroblasts from which the immunogen was obtained had been cultured in heterologous sera which do not themselves contain the antigen. Antigen was released into the medium of cells cultured in calf serum and its presence in chicken serum would suggest that it is also released from fibroblasts *in vivo*. The concentration of the antigen in chicken serum was estimated at several μ g per ml and is, therefore, much higher than the amounts of histocompatibility antigens and carcinoembryonic antigen which can also be detected in sera.

These two reports both show that one cannot always readily distinguish between membrane and serum proteins, let alone between 'true membrane proteins' and 'extracellular proteins'. In the

case of the fibroblast surface antigen the obvious interpretation is that the cells synthesise the antigen which, after a period at the cell surface, falls off into the serum. Whether the situation is the same or the reciprocal in the case of β_2 -microglobulin, it is clear that no firm line can be drawn which defines certain molecules as membrane proteins and others as non-cellular. The membrane rather than having an end, tails off into the medium. This is not a doctrine of despair for those hoping to define the molecular composition of cell membranes. Rather, it suggests the need for a more precise description of the molecular arrangement in temporal as well as topological and topographical terms.

Earth spin theory queried by doubting Thomas

by our Cosmology Correspondent

THE Ordinary Meeting of the Royal Astronomical Society held on March 8 was notably lively and lighthearted. The tone was set early in the proceedings, when the secretary, reading out the list of presents received encountered the item "De Witt and De Witt, 'Black Holes', presented by Mr Grey"; this provoked an appropriate audience response.

Even after the preliminaries, however, things did not immediately settle down into the technicalities of specialist papers; the first speaker, D. D. Thomas (Royal Greenwich Observatory), described "recent variations in the rotation period of the Earth", a topic which clearly aroused great interest among the majority of the fellows present, whatever their own specialist interests. The reason for presenting this item at this particular meeting was, Thomas said, the excessive press interest in the change in the length of the day (LOD) which occurred in December 1973.

As Thomas explained, this jump in the LOD was far from being an unusual event. A similar effect occurred in the preceding winter, and changes of the order of a millisecond in the LOD are not uncommon, although it is true that they occur more frequently in summer than in winter. And indeed the December 1973 event may not even have been very sudden, since the data show only that it occurred within a period of about 3 weeks. So why did it arouse such interest? Perhaps, Thomas suggested, the press were unusually sensitive to astronomical stories at that time, because of Comet Kohoutek.

Thomas then went on to discuss the variations in the LOD in more general terms. It is now generally accepted that seasonal changes in the rate at which

the Earth spins are caused by seasonal changes in the general circulation of the atmosphere, and he argued that meteorological effects could well be responsible for sudden changes in the LOD as well. He cast doubt on the reliability of evidence that earthquakes or sunspots might be causes of changes in the LOD. This is not to say that the overall trend in the acceleration of the Earth could not be influenced by solar activity, but "it is dangerous to argue a causal relationship between specific solar events and changes in the LOD".

Around the time of the recent Earth spin event, there were, it seems, changes in the pattern of westerly winds at the 500 mbar level, but Thomas declined to be drawn onto dangerous speculative ground, closing his talk with an emphatic statement that he would not attempt to say what causes the meteorological variations. As readers of the News and Views section will be aware, however, there is now compelling evidence that solar activity affects the very meteorological processes which seem to affect the LOD (see *Nature*, 246, 384; 1973).

Earth plates as membranes

from our Geomagnetism Correspondent

In recent years several workers have sought to explain the origin of major tectonic activity away from plate boundaries in terms of hot spots, with or without associated mantle plumes. The best known example of the use of such an interpretation is probably the Hawaiian-Emperor island chain which is seen as the surface trace resulting from the motion of the Pacific plate over a stationary or near stationary magma source; but continental graben and rift valleys, such as the Rhine graben, have also been associated with hot spots. On the other hand, there are problems with this viewpoint and there are alternative, if no less contentious, explanations for both continental and oceanic mid-plate tectonic structures. The Rhine graben, for example, has an average width of 36 km and an estimated extension across the valley of 4.8 km; but it is not entirely clear how such features could result from hot spot or plume activity. And as far as the formation of the Hawaiian islands is concerned, the hypothesis that the chain derives from a propagating tensional fracture in the lithosphere which causes volcanic activity as it extends was put forward as early as 1942 and still receives much support today.

The chief difficulty with both the older and newer interpretations of the Hawaiian chain lies in substantiating them, although the former was recently

given a significant boost by Turcotte and Oxburgh (*Nature*, 244, 337; 1973) who offered two possible origins for the required tensional stresses. The first of these involved thermal effects. Lithosphere created at an oceanic ridge by the cooling of mantle material cools further and increases in thickness as it moves away from the ridge. Such an elastic plate cooled non-uniformly will be subject to thermal stresses in the form of tensions which are parallel to the ridge, and thus aligned with the corresponding magnetic anomalies, but normal to fracture zones. Turcotte and Oxburgh were able not only to calculate the thermal stresses and show them to be sufficient to fracture the lithosphere but also to predict the direction of the tensional thermal stresses near Hawaii and show it to be in close agreement with a similar prediction using the theory for the plastic yielding and fracture of elastic solids.

The second type of tensional stress, the theory of which has now been developed at greater length by Turcotte (*Geophys. J.*, 36, 33; 1974), is the membrane stress arising from non-spherical plate tectonics. The basic point here is that if the Earth were a perfect sphere plates would be able to move about without deformation but, because the Earth is in fact an oblate spheroid with an ellipticity of 0.00335, the lithosphere must deform when its latitude changes. A small plate at the equator, for example, will have two principal radii of curvature (6,378 km and 6,335 km), both of which will increase if the plate moves towards higher latitudes and both of which reach 6,400 km for a plate at either of the poles. Conversely, a small plate moving towards the equator will have its principal radii of curvature decreased. Normally such changes in the radii of curvature would produce bending stresses, but because the surface plates in this case are thin compared with the Earth's radius they will behave as thin shells in which the bending stresses may be neglected in comparison with the membrane stresses arising from stretching the plates to different radii of curvature.

In principle, therefore, it should be possible to determine the membrane stresses associated with the deformation of the Earth's moving plates using the already developed theory of thin shells—and this is what Turcotte has tried to do. For an unstressed thin shell whose radii of curvature are increased, the result will be a tension at the edge and a compression in the interior; for a decrease in the radii of curvature the situation will be reversed. But, first, do such membrane stresses actually exist in real plates? Plates move with velocities in the range 1-10 cm yr⁻¹, thus requiring about 10⁸ yr to undergo a significant change in latitude. It is usual

to regard the lithosphere as an elastic medium on a short time scale; but on the geological time scale will plastic yielding occur, relieving the membrane stresses? As Turcotte points out, at "modest" depths plastic yielding is to be expected because of the higher temperatures involved. But he also notes that the relief of membrane stresses requires plastic flow throughout the whole thickness of a plate and that there is abundant evidence (for example, from major fault systems) for the absence of long term plastic flow in near surface rocks.

Having disposed of this point (which is not the Aunt Sally it might at first seem), Turcotte goes on to develop the theory of membrane tectonics, generally along the lines mapped out by Novozhilov (*The theory of Thin Shells*, Noordhoff, 1959). For the real Earth the determination of the membrane stresses is, of course, an insolubly complex problem; surface plates have irregular shapes and each element of each large plate has its own radii of curvature which change in accordance with the particular variation in latitude. Turcotte thus adopts a highly simplified model in which the initially unstressed plate is represented by a circular segment of a spherical shell and in which the deformed plate is a similar spherical dome but with a slightly larger or smaller radius of curvature. In this scheme, deformation is produced by a radial surface force on the shell.

What emerges from this analysis is that a change in the latitude of the modelled lithosphere can result in membrane stresses of up to several kilobars. The stress required to produce a fracture in the real lithosphere is not precisely known, although stresses on active fault zones are known to be of the order of 0.1 kbar and laboratory work has shown the strength of mantle rocks to be of the order of 10 kbar. It may thus be fairly safely presumed that membrane stresses of several kilobars would indeed be sufficient to fracture the lithosphere, although thermal stresses and the stresses driving the plates may also play a part. Turcotte further shows that membrane stresses of about 2 kbar should lead to gravity anomalies of the order of 10 mgal, which is the magnitude of the anomalies actually observed.

Whether or not the importance of membrane stress is substantiated, Turcotte's analysis can only strengthen the hand of workers such as Jackson and Wright (*Petrology*, 11, 405; 1970) who see the Hawaiian chain in terms of a propagating fracture rather than a hot spot. Moreover, membrane stresses seem to be the more capable of explaining the finite extension of rift valleys—as the extension needed to relieve the stresses.

West Atlantic abyssal circulation during the past 120,000 years

Detmar Schnitker

Department of Oceanography, University of Maine, Walpole, Maine 04573

Three faunal assemblages of benthic foraminifera are associated with the three abyssal water masses of the West Atlantic. Faunal distribution 15,000 yr ago indicates cessation of Arctic bottom water flow and a modified supply of Antarctic Water during the last full glacial period, resulting in an apparent warming of the bottom water. Faunal distribution and thus the deep sea circulation were similar to present conditions during the last interglacial 120,000 yr ago.

STUDIES of the remains of planktonic microorganisms from deep sea sediments reveal the climatic and oceanographic fluctuations that occurred in the surface waters of the world's oceans during the late Tertiary and particularly the Quaternary¹⁻⁶. Early studies of the abyssal benthonic foraminifera pointed to an apparent homogeneity of the deep-sea faunas⁷⁻⁹. Probably the past experience of micropaleontologists working within small areas and with very variable shallow water faunas made them insensitive to, or suspicious of, the small but real differentiations that can be found in deep-sea material.

Living (preserved) and total (empty shells) benthonic foraminiferal faunas were studied from West Atlantic sediment samples. Among the approximately 150 species of calcareous foraminifera of this area, three consistently recurring assemblages can be recognised whose areal distribution is shown in Fig. 1. Each of these assemblages is named after its most conspicuous member species and is closely associated with one of the three abyssal water masses that are present in the West Atlantic Ocean. The first, or *Epistominella exigua* fauna, occurs in its pure form in samples north of 45°N latitude only and is contained within the contours of the 1.9° C potential temperature of the Arctic bottom water, as shown by Worthington and Wright¹⁰. The second faunal assemblage, dominated by *Osangularia umbonifera*, is best defined within the 1.5° C potential temperature contour of the Antarctic bottom water, south of 30°N latitude. The transition from the *E. exigua* fauna to the *O. umbonifera* fauna is at approximately 35°N latitude, the area where the Arctic and Antarctic bottom water meet and lose their identity¹⁰. That indeed the water characteristics and not bathymetry control the faunal distribution is shown by the *Epistominella exigua* fauna which occurs at shallower depths in the northern portion of its range than further south, thus paralleling the descent of the Arctic bottom water from 500 m at the Denmark Straits to nearly 5,000 m north of Bermuda. Samples located on the continental rise and slope and on the mid-Atlantic ridge contain faunas in which several species of *Hoeglundina*, *Uvigerina* and *Gyroidina* are abundant. With a few exceptions these samples are contained between the 2° C and 4° C potential temperature contours. These faunal assemblages are associated with the lower North Atlantic deep water.

Disagreement between the postulated association of faunal assemblages and water masses appear to exist for four samples

collected within the Gibbs fracture zone, at the southern end of the Reykjanes Ridge. These samples contain typical *Epistominella exigua* assemblages, thus inferring the presence of Arctic bottom water at these sites. According to Worthington and Wright¹⁰ this area should be occupied by North Atlantic deep water. An easterly flow of bottom water through the fracture zone has recently been suggested^{11,12} and is supported here by faunal evidence. In a few areas, such as on portions of the Hatteras and Nares abyssal plains, the distribution of bottom faunas has been inferred only: carbonate solution at these great depths has modified the composition of the faunal assemblages and, in a few samples, nearly eliminated them altogether.

The information gained from the distribution of the present faunas can be applied to those of the past. Figure 2 shows again the distribution of three faunal assemblages for the latter part of the last glacial period. The core samples were taken from the upper part of the y-zone of Ericson *et al.*⁵, or the 17,000 yr BP level of the Climate/Long Range Investi-

FIG. 1 Distribution of foraminiferal assemblages in the present western Atlantic Ocean. ●, Surface sample.

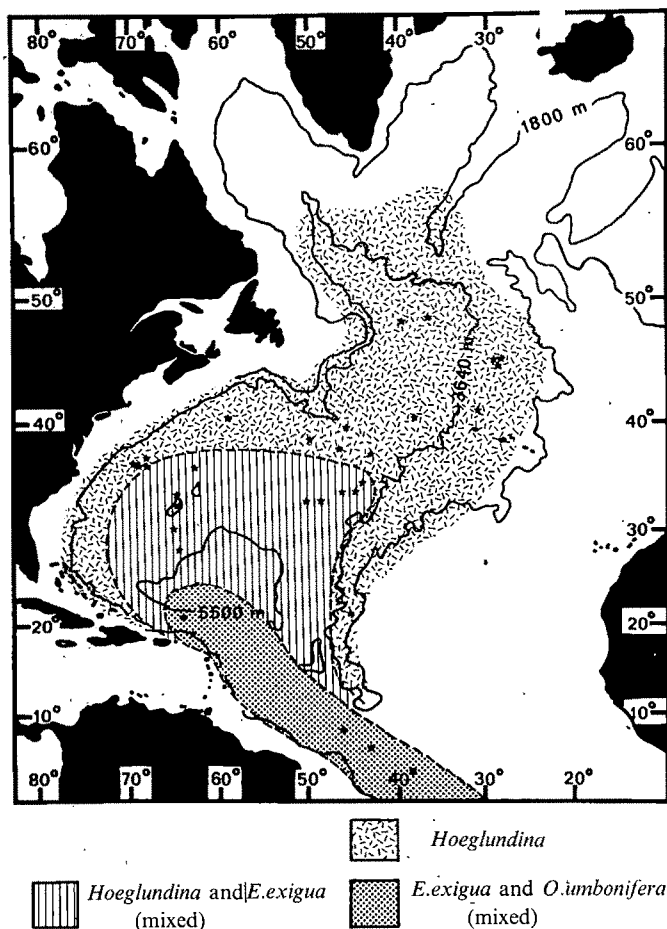

FIG. 2 Distribution of foraminiferal assemblages under glacial conditions, 17,000 yr ago. ★, Core location.

gation Mapping and Predictions (CLIMAP) programme. Only one of the faunal assemblages of the present time existed during late glacial times, the *Hoeglundina* fauna, which at this time has invaded nearly all of the western Atlantic basin north of 40°N latitude. Towards the south, more and more elements of the *Epistominella exigua* fauna are represented so that south of 40°N latitude the bottom fauna gains a new identity as a *Hoeglundina-Epistominella exigua* mixed assemblage. Further south the faunal characteristics change again through a progressive increase of elements of the *Osangularia umbonifera* fauna and a concomitant decrease of the *Hoeglundina* fauna, so that south from about 22°N latitude the bottom fauna can be termed the *Epistominella exigua-Osangularia umbonifera* mixed assemblage.

Such a change in faunal composition and distribution was probably brought about by a change in the deep water circulation pattern and/or a change in the character of the water masses. Apparently, Arctic bottom water was not present and Antarctic bottom water, if it continued to enter the region, must have had characteristics different from those of modern Antarctic bottom water. A water mass with characteristics similar to those of modern Atlantic deep water occupied the entire northern portion of the basin, whereas a water mass which was probably produced by mixing of the northern and southern waters occupied the central portion of the basin.

Figure 3 shows the faunal distribution pattern for a time approximately 120,000 yr ago, towards the end of the last interglacial stage. The faunal assemblages and their distributions are nearly identical to those of today.

Such drastic changes of the deep thermohaline circulation between glacial and interglacial stages within the Atlantic Ocean have been proposed by Weyl¹³: reduced evaporation

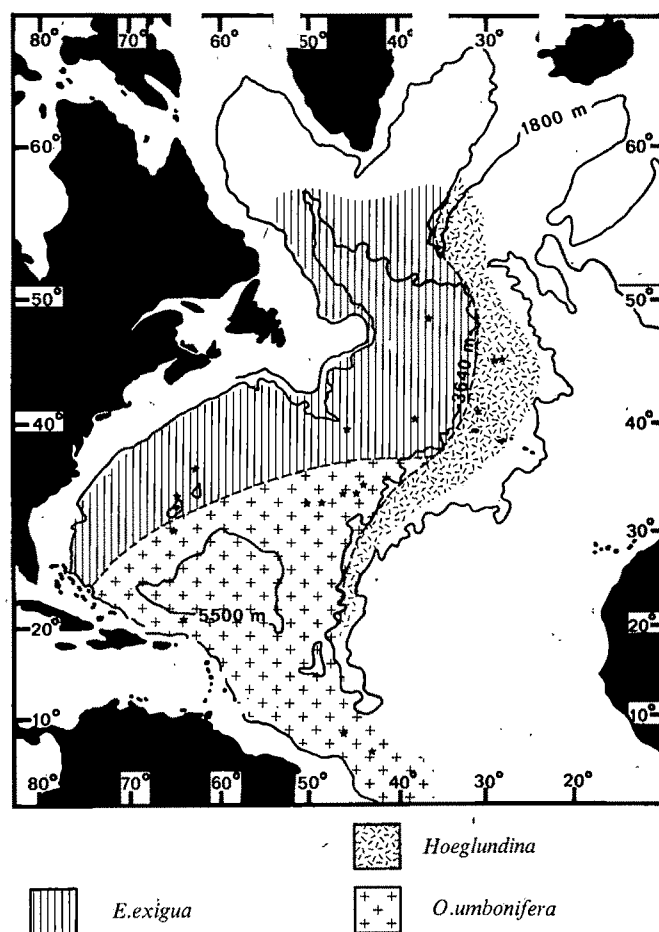

FIG. 3 Distribution of foraminiferal assemblages under interglacial conditions, 120,000 yr ago. ★, Core location.

in low latitudes led to the inflow of lower salinity water into the Norwegian Sea which then acquired a stable density stratification and a cover of sea-ice. Formation of Arctic bottom water ceased. A similar density stratification in the Antarctic would also have prevented the formation of Antarctic bottom water. A subpolar gyre was to form between the sea-ice front, south of Iceland and the subtropical

FIG. 4 Schematic N-S diagram of thermohaline circulation in West Atlantic Ocean under, a, interglacial and, b, glacial conditions. Modified from Weyl¹⁰. [E], Low density surface water; ■, sea ice. convergence, then at about 40° to 45°N latitude. Glacial bottom water which formed in this subpolar gyre, with temperatures similar to those of the present Atlantic deep water, was to be the only bottom water of the entire Atlantic Ocean. Figure 4 shows the generalised scheme of the Atlantic deep water circulation, modified from Weyl¹³, for glacial and interglacial conditions.

In the previous discussion specific qualities, such as temperature, salinity or dissolved oxygen content, have been purposely avoided and the general term 'water mass' used instead. Experience suggests that temperature may well be the most significant factor controlling the faunal composition and distribution. The present-day transition from the *Epistominella exigua* fauna to the *Osangularia umbonifera* fauna, however, takes place where both the Arctic and the Antarctic bottom water masses have reached a potential temperature of 1.9° C. The temperature in the transition area being equal for the two water masses, other factors, such as salinity or dissolved oxygen must be responsible for the faunal differentiation. The analytical techniques developed by Imbrie and Kipp⁶ may permit a quantitative assessment of the various environmental factors.

This work was supported by a National Science Foundation grant. Surface samples were collected from the RV *Trident* (University of Rhode Island), the RV *Eastward*

(Duke University) and the RV *Gulliss* (University of Miami). Core samples were made available by the Bedford Institute of Oceanography and the Lamont-Doherty Geological Observatory of Columbia University.

Nematocyte migration in *Hydra* influenced by tissue polarity

Rosalind L. Herlands & Hans R. Bode

Department of Developmental and Cell Biology, School of Biological Sciences, University of California at Irvine, Irvine, California 92664

In Hydra, migration of the desmoneme nematocytes takes place only in the direction of tissue polarity as defined by which end will regenerate a head.

THERE are many examples of cells that migrate as individuals through tissue or water to specific sites. Some of the influences involved in the apparently directed migration of these cells have been elucidated. Chemotaxis has been demonstrated in the aggregation of slime mould cells¹, in the movement of sperm toward the gonangium in the hydroid, *Campanularia*², and in the migration of leukocytes and lymphocytes to areas of infection^{3,4}. The orientation of the substratum upon which the cells migrate is known to orient the movements of cells *in vitro*⁵, and may well play a similar role in the organism. In other cases the movement may not be directed. Instead, cells migrate randomly until they reach the appropriate tissue where specific cell-cell contacts are made preventing any further movement. This mechanism has been postulated for the migration of primary mesenchyme cells in sea urchin embryogenesis⁶, and for the reconstitution of tissue layers from aggregates of cells^{7,8}. Here we describe an unusual type of influence which affects the migration of one type of nematocyte in *Hydra*, namely the polarity of the tissue. The mechanism underlying this influence may eventually prove to be one of those described above.

In *Hydra attenuata* four types of nematocytes (stinging cells) arise by differentiation from interstitial cells in the ectodermal layer along most of the body column^{9,10}. Each type is easily identifiable by the distinctive shape of its nematocyst. More than 80% of the mature nematocytes (H. R. B., and K. Flick, unpublished) migrate through the ectodermal layer¹¹ into the tentacles where they are mounted in pockets in the epithelial cells of the ectoderm. Desmoneme and atrichous isorhiza nematocytes are found only in the tentacles, whereas stenotele and holotrichous isorhiza nematocytes are mounted in the ectoderm throughout the body as well as in the tentacles.

Grafting and nematocyst migration

The large % of nematocytes in the tentacles suggests that when the nematocytes become mature they preferentially migrate in an apical direction. Vögeli¹² has shown that, indeed, small non-epithelial cells in the ectoderm do migrate preferentially in an apical direction. We have obtained more detailed evidence that supports this view. We grafted upper halves of *Hydra* (H123 in Wolpert's scheme¹³) labelled with ³H-thymidine to unlabelled lower halves (4B56F), and the reciprocal of labelled lower halves grafted to unlabelled upper halves. By periodically thereafter examining the unlabelled halves for labelled nematocytes, we found that nematocyte migration is strongly biased in an apical direction (R. L. H., and H. R. B., unpub-

FIG. 1 Grafting procedure for analysing the migration of labelled nematocytes with or against tissue polarity. Dashed lines indicate sites of cutting. The pieces of tissue were removed and grafted together with the head at either *a*, the apical end of the gastric region or *b*, the basal end of the gastric region. Animals (cross-hatched) were labelled by injecting ^3H -proline into the gastric cavity one day before grafting.

lished). In fact, basal migration was found only if a bud was present, and then the nematocytes migrated into the bud. Migration into the peduncle is almost non-existent. These experiments indicate that the migration pattern of nematocytes is not simply one of random movement coupled with entrapment in the battery cells of the tentacles, but actually is one of preferential apical migration.

Once having reached the tentacles, nematocytes remain there and do not diffuse or migrate back into the body column. Campbell¹² has shown that by grafting a head containing nematocytes labelled with ^3H -thymidine to an unlabelled body that there is no measurable migration of labelled nematocytes into the body region. Further, large numbers of septate desmosomes between nematocytes in pockets of epithelial cells and the epithelial cells have been seen^{12,14} suggesting that once a nematocyte is mounted in a pocket it is permanently immobilised. Thereafter, the nematocyte remains on the tentacle until discharged or sloughed off with its host battery cell at the end of the tentacle. As the tentacles are in continuous growth¹¹ and the entire tentacle is renewed in about 6 d (H. R. B., and K. Flick, unpublished), the turnover of nematocytes is relatively rapid.

Chemotaxis or tissue polarity?

The apical directionality of migration may simply be due to a chemotactic attraction towards the head, or it may be due to some property of the tissue in the body column. The two possibilities can be distinguished by grafting a head to the basal end of a piece of the body column. In this case, if nematocytes are to migrate into the head, they must migrate in a basal, not the usual apical, direction. If nematocytes are guided by chemotaxis to the head, the position of the head at the apical or basal end should not affect rates of accumulation of nematocytes in the tentacles. If, however, some relatively stable property of the tissue influences the nematocytes to move selectively in an apical direction, one would expect to find much less accumulation of nematocytes in a basal head compared to an apical head. The following experiment was carried out to examine this.

Unlabelled heads of *H. attenuata* (hypostome and tentacles) were grafted to either the apical or the basal end of the gastric region of animals labelled with ^3H -proline (Fig. 1). In basal grafts, the host head was removed 3–5 h after grafting which inhibited regeneration of a head at the apical end during the course of the experiment. Wilby and Webster¹⁵ found similar results for basal grafts of *H. littoralis* while Wolpert *et al.*¹⁶, also using *H. attenuata*, left the host head on for 8 h to prevent regeneration. The nematocyst capsules were heavily labelled as was expected, since proline and hydroxyproline occur in large quantities in these structures¹⁷.

The accumulation rates of labelled desmonemes and stenoteles were measured as follows: periodically the heads

of five to eight grafts were removed and dissolved in 0.1 N NaOH plus 2.5% sodium dodecyl sulphate. The nematocysts, the only structures which survive this treatment, were analysed autoradiographically to determine the % of desmoneme and stenotele nematocysts that were labelled. The analysis was limited to these two types because they occur in greater numbers than do the two types of isorhizas and their distributions in the animal differ: desmonemes are mounted only in the tentacles whereas the stenoteles are mounted along the body column as well as in the tentacles. It should be noted that the time required for a mature nematocyte to migrate from the body column into the tentacles is short (less than 6 h), (R. L. H., and H. R. B., unpublished), and therefore, is not a factor in this analysis. The results (Fig. 2) indicate that the stenoteles accumulate at the same rate in the tentacles of a head grafted to the basal end of the gastric region as in one grafted to the apical end. In contrast, desmonemes accumulate in the tentacles of an apical head at a greater rate than in the tentacles of a basal head during the first three days. The difference between the rates of accumulation in apical and basal heads is significant (*t*-test, $P < 0.01$) on days 2 and 3, but not on any other day. Desmoneme migration, therefore, appears to be polarised. The fact that desmonemes accumulate at all in basally grafted heads, and the increasing migration rate into these heads after 3 d, might be interpreted, as the result of a gradual reversal of the direction of desmoneme migration under the influence of the basally grafted head.

Regeneration polarity

In this connection it is interesting to consider the effect of basally grafted heads on regeneration polarity in *Hydra*. The tissue of the body column is said to be polarised, as a piece of the column when removed will under normal circumstances always regenerate a head at the apical end and a foot at the basal end. Using *H. littoralis*, Wilby and Webster¹⁸ grafted heads to the basal ends of isolated gastric regions, removed the heads after a variable period, and examined the regeneration characteristics of the original gastric regions. They found that the pieces left in the graft combination for 1–2 d subsequently regenerated with the original polarity, that is, a head at the apical end and a foot at the basal end. After 4–5 d in the graft, the head regenerated at the basal end and a foot at the apical end. Thus, the basally grafted head reversed the regeneration polarity of the tissue. We repeated this experiment with *H. attenuata* (Table 1) and obtained similar results: regeneration with the original polarity after 1–2 d in the graft combination; intermediate forms such as bipolar animals

FIG. 2 Rate of accumulation of (a) stenoteles and (b) desmonemes in heads grafted to either the apical end (O) or the basal end (●) of a gastric region. The experiment was carried out twice. Each point represents the average value of 10–15 heads analysed individually. The difference between the rates of accumulation of desmonemes in apical and basal heads is significant (*t* test, $P < 0.01$) on days 2 and 3, but not on any other day.

TABLE 1 The effect of basal head grafts on host polarity

Time of proximal head removal (h)	No. of grafts	Original polarity	Type of regeneration and Apical head		Reversed polarity
			proximal tentacle	Bipolar	
24	10	7	1	2	0
48	10	5	1	3	1
72	10	2	2	5	1
96	7	2	0	1	4
120	7	0	0	1	6

For basal head grafts, the host head was removed 3–5 h after grafting a head to the basal end of the gastric region. As had been demonstrated earlier (R.L.H., and H.R.B., unpublished), removing the host head at this time instead of at the time of the basal head graft prevented normal head regeneration at the apical end. During the course of the experiments, which were carried out at $20 \pm 1^\circ\text{C}$, the animals were not fed, they did not bud, and no head regeneration at the apical end occurred while a head was attached to the basal end of the gastric region.

The four regenerating forms are defined as: original polarity, head regenerating at apical end; apical head and basal tentacle, head regenerates at the apical end and a single tentacle forms at the basal end; bipolar, heads regenerate at both ends; reversed polarity, a head regenerates at the basal end. The table represents the pooled data of two experiments.

(a head at both ends) after 2–3 d; and after 4–5 d in the graft, reversal of polarity. The intermediate forms were to be expected since the reversal of polarity is a gradual process: tissue near the basally grafted head is reversed sooner than the tissue near the original apical end or the gastric region as a whole (R. L. H., and H. R. B., unpublished). The kinetics of polarity reversal seem to parallel the kinetics of desmoneme migration into a basal head: slow at first, and rapidly approaching 100% after 4 d. Thus, the results are consistent with the idea that the direction of desmoneme migration is correlated with the regeneration polarity of the tissue.

A second experiment similar to the first provided more evidence supporting this hypothesis. In addition to grafting a head to the basal end, a peduncle was grafted to the apical end (Fig. 3). Wilby and Webster¹⁸ showed that this combination would reverse the regeneration polarity of the gastric region in 1–2 d instead of the 4–5 d necessary if only a head were grafted to the basal end. When we repeated this experiment with *H. attenuata* (Table 2), we also found rapid polarity changes: after 24 h, only one of 11 gastric regions regenerated according to its original polarity; polarity reversal was observed in more than half of the cases. The rates of nematocyte accumulation into apical and basal heads were measured as before. In this case (Fig. 4) there is no indication that the desmonemes migrate accord-

TABLE 2 The effect of basal head and apical peduncle grafts on host polarity

Time of head and peduncle removal (h)	No. of grafts	Original polarity	Type of regeneration			Reversed polarity
			Bipolar	Bipeduncle		
24	11	1	2	2		6
48	13	1	1	1		10
72	13	1	0	0		12
96	15	0	0	0		15

Both head and peduncle were grafted to the gastric region at the same time in both combinations. During the course of the experiments, which were carried out at $20 \pm 1^\circ\text{C}$, the animals were not fed and they did not bud.

The regenerating forms are the same as described in Table 1. Bipeduncle represents a peduncle which regenerates at both ends and in which no head is formed at all. The data is the sum of two experiments.

ing to the original regeneration polarity. If anything, the rate of accumulation of desmonemes is slightly greater in the basal than in the apical head, but the difference is not significant (t test, $P < 0.05$, except at 2 d). As before, the accumulation rate of stenoteles is the same for a head at either the basal or apical end of the piece of tissue.

Regeneration gradients

The correlation of regeneration polarity and direction of desmoneme migration which we have observed in two experiments suggests that desmonemes may be guided by the 'gradients' which are thought to control regeneration. Little is known about the nature of these gradients although several hypotheses have been put forward^{19–23}. In Wolpert's terms one could say that the desmonemes 'measure' the positional value of the cells they are moving over and migrate only in the direction of increasing positional value (with respect to head formation). During the reversal of polarity because of the basal head graft, the gradient of positional value is inverted, and the desmonemes continue to migrate 'up' the gradient, which is now towards the basal end of the gastric region. In this regard, our results also provide evidence that the changes which occur during the reversal of regeneration polarity of a gastric region occur throughout the piece, rather than being confined to the terminal cells which actually produce the new head and foot.

The mechanism underlying the active migration of desmonemes into the tentacles, or the 'measurement' of positional value, could be based on contact guidance, a restricted form of random movement (excluding basal migration), or some form of chemotaxis. The last is initially attractive because there is some evidence that diffusible substances play a role in the gradients of *Hydra*^{19,22} as well as in other systems such as the insect epidermis^{24,25} but it is doubtful that the desmonemes respond directly to these substances.

In *Hydra*, inhibition of head formation behaves as a gradient of substance diffusing from the head region. The gradient is very labile, vanishing within several hours after removal of the head²⁶. Also, grafting a head to the basal end of a piece of the gastric region establishes a new inhibition gradient, this time with the high point of the basal end, within 3–8 h (see above and refs 15 and 16). If the desmonemes were directly influenced by the gradient of inhibition, or gradient of positional signal¹⁹, one would expect them to migrate into basal tentacles in large numbers after 8 h, and not after 3 d as was observed. Because the properties of the inhibition gradient are not consistent with the observed desmonemes migration behaviour, the desmonemes probably do not 'read' this gradient.

Another possibility is that the desmonemes may respond to a substance diffusing from a graded distribution of sources along the length of the body column, whose density is highest at the apical end²². However, the rapid change (24 h) in tissue polarity in the second graft combination that we and Wilby and Webster¹⁸ observed would require an equally rapid reversal in the graded distribution of sources, or cell

Fig. 3 Grafting procedure for analysing the effect of the peduncle on accumulation rates of nematocytes in basal or apical heads. Dashed lines indicate sites of cutting. The head and peduncle were grafted to the gastric region either *a*, in the original orientation or *b*, in the inverted orientation. Animals (cross-hatched) were labelled by injecting ^3H -proline into the gastric cavity.

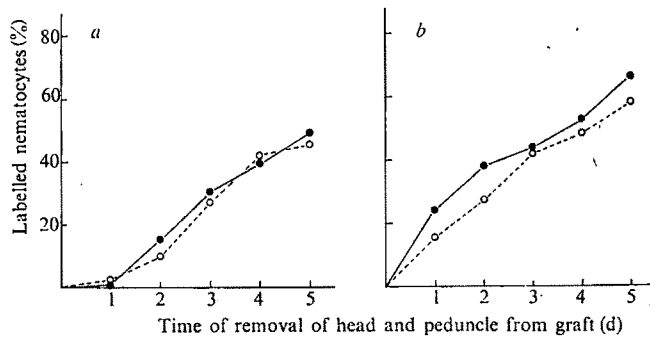

FIG. 4 Rate of accumulation of stenoteles (a) and desmonemes (b) in heads grafted to either the apical end (O) or the basal end (●) of a gastric region in the presence of a peduncle grafted to the opposite end. The experiment was carried out twice and each point represents the average value of 10–15 heads analysed individually. For the desmonemes, the differences between control and experimental points are not significant at the $P = 0.05$ level, but the second day point is significant at the $P = 0.02$ level.

type, which seems unlikely. This evidence would also appear to render untenable any theory in which tissue polarity is due exclusively to the graded distribution of a particular cell type.

Stenotele migration

In contrast to desmoneme migration, stenotele migration is not affected by the polarity of the tissue. Stenoteles will migrate into basally-grafted heads as rapidly as they will into apical heads. This is not simply the result of random movement coupled with entrapment in the tentacles for, as mentioned earlier, in normal animals stenoteles migrate almost exclusively in an apical direction. Only if a bud is present will stenoteles migrate basally (R. L. H., and H. R. B., unpublished), as stenoteles always migrate toward a head region, some form of chemotactic attraction to the head is probably involved.

Thus, desmoneme and stenotele migration are, at least in part, affected by different influences. Though other hypotheses can be constructed to explain the rates of ac-

cumulation of desmonemes in apical and basal heads, these hypotheses must take into account the rather different rates of accumulation of stenoteles and desmonemes in the basal heads in the first experiment. This renders unlikely those hypotheses based on a systematic difference in the experimental design, for such a difference would be expected to affect both nematocyte types in the same way.

Super-relativistic phase velocities of radio source components

R. H. Sanders

National Radio Astronomy Observatory, Green Bank, West Virginia

A sudden injection of relativistic electrons at the centre of an extended dipolar magnetic field could lead to an apparent faster-than-light expansion of two synchrotron emitting regions. Subsequent injections of electrons would produce components which move outwards along the same axis.

INTERFEROMETRIC radio observations with transcontinental baselines reveal rapid fluctuations in the fine structure of some extragalactic radio sources,^{1,2} and in at least three cases these fluctuations imply expansion of small radio components at

velocities apparently greater than that of light, if these sources are at the distances indicated by the cosmological interpretation of their redshifts. In the case of the QSOs 3C279 and 3C273, the apparent separation velocities of double components are 6c and 4c respectively.² For 3C120, which has been variously designated as a Seyfert or N-type galaxy, the apparent separation velocity is 3c (ref. 3). BL Lac has also exhibited qualitatively similar rapid changes in structure. More recent observations indicate that the actual structure might be more complicated than the original simple models but the problem of explaining apparent faster-than-light motions of source components persists.

Classes of models

One might expect apparent faster-than-light expansion motions of relativistically separating components, if the direction of the motion is almost along the observer's line of sight⁵, but such models require somewhat contrived conditions⁶. Moreover, accumulated observations seem to reveal that these apparent faster than light motions are a not uncommon property of compact radio sources, whereas expulsion of components within 10° of the observer's line of sight is improbable.

A second possible explanation of this phenomenon is the "Christmas tree" model in which the radio source is assumed to consist of a number of independently blinking components spread over an extended region⁷.

There are three possible difficulties with this model. First, the luminosities of the blinking components must change such that limitations on the total flux variations from the source are not violated. Second, there should be just as many apparent super-relativistic contractions as expansions in radio sources. Third, in a truly random distribution of blinking components the position angle of the line connecting the two dominant components should also be a function that varies with time; in at least two cases, 3C279 and BL Lac, this position angle seems to be constant^{2,4}. Dent⁸ has answered this objection by suggesting that these random events are occurring in a disc seen edge on but this is improbable if the constancy of position angle is a general property of these sources.

A third possible class of models for sources with rapidly variable structure involves phase velocities of components^{1,9}. The specific model suggested here is of this class.

Particle injection in a strong dipolar field

I assume that the magnetic field of such a source has a dipolar form. The energy and relativistic particle source of the quasar is at the centre of the dipole, and far from this central object¹⁰ the magnetic field lines satisfy the polar coordinate equation

$$r = R_0 \sin^2 \theta \quad (1)$$

Variables are defined as shown in Fig. 1. For simplicity I assume that the observer's line of sight is perpendicular to the axis of the dipole.

At time $t_0 = 0$ a burst of relativistic electrons is emitted by the central object, and I assert that the total energy of these electrons is less than the total magnetic field energy of the dipole. So a train of electrons, the length of which is determined by the duration of the burst, will move out along every field line. The pitch angles of these electrons will be small for two reasons. First, the magnetic field strength drops off rapidly ($\sim r^{-3}$), and the quantity P_{\perp}^2/B (where P_{\perp} is the momentum of the electrons perpendicular to the magnetic field, B) is an adiabatic invariant of the electron motion. Second, electrons with high pitch angle will lose energy rapidly by synchrotron radiation in the central region of high field. Therefore, as the train of electrons travels out along the field lines, their synchrotron radiation will be confined to a narrow cone along the field line, and will not be directed toward the observer. At some time t_1 , however, when the train has reached r_1' (Fig. 1), the 'search light' of the electron train will sweep past the observer, who will see a synchrotron spot at a projected distance d_1 from the central object when the radiation reaches him. Since the dipolar field is symmetric about the equatorial plane, the observer will see two such spots separated by a projected distance of $2d_1$.

At a later time, t_2 , this train of electrons will have moved over the top of the field line and, still emitting synchrotron radiation forwards, will no longer be visible. But a similar train traveling along a higher field line will have reached r_2' at a projected distance of d_2 from the central object. The

two synchrotron spots will now have increased their separation to $2d_2 > 2d_1$. Thus, the radio source will seem to have two components separating with an apparent velocity of

$$V_s = 2(\Delta d)/\Delta t \quad (2)$$

where $\Delta d = d_2 - d_1$. Δt is not the difference in travel times of the two electron trains ($t_2 - t_1$), but the difference in arrival times of the synchrotron radiation from r_2' and r_1' at the observer. Radiation coming from r_2' has less far to travel to reach the observer (by a distance x), so

$$\Delta t = t_2 - t_1 - x/c \quad (2a)$$

where $x = \Delta d \tan \theta$.

This apparent separation velocity (equation (2)) does not represent the motion of two objects; it is a phase velocity of the emission region and is not physically limited by the velocity of light.

For a perfect dipolar field, equation (2) can be solved explicitly to obtain a numerical value for the apparent separation velocity of the synchrotron spots: $V_s = 4.4c$.

This model does not depend on the observer being in the equatorial plane of the dipolar field. In general, one will always observe two separating synchrotron spots regardless of orientation unless the line of sight is coincident with the axis of the dipole, in which case the observer will see an expanding ring. With impulsive injection of electrons, the apparent expansion velocities for orientations other than that described above will be less than $4c$ but greater than $2c$. Further, it is interesting that if particle injection were continuous instead of impulsive, one could see continuous synchrotron radiation along a line corresponding to the projection of the magnetic dipole axis on the plane of the sky—a jet.

Individual source parameters

Several conditions enable estimation of the physical parameters of individual sources. If: (a) the magnetic field is dipolar in form; (b) the energy density of the field is higher than that of the particles; (c) the relativistic particle energy density must be sufficiently great to explain the total radio luminosity up to a frequency of 50 GHz or so; and (d) the pitch angles of the radiating electrons must be less than 10° in the emitting regions; then with the measured separation of the double components in a particular source we may estimate the size (a) of the region over which particle acceleration takes place (that is, the radius of the equivalent current loop producing the dipolar magnetic field), the magnetic field strength in this region (B_0) and the total magnetic field energy (E_H). Assuming cosmological distances (Hubble's constant = 75 km s⁻¹ mpc⁻¹; $q = 1$) I find for 3C120 (ref. 3) $a = 0.3$ pc, $B_0 = 1.0$ gauss; $E_H = 3 \times 10^{53}$

FIG. 1. Dipolar field geometry of a rapid variable structure radio source. *a*, Particle burst injected at $t_0 = 0$; *b*, line of sight.

erg; and for 3C279 (ref. 1) $\alpha = 5$ pc, $B_0 = 0.3$ gauss; $E_H = 3 \times 10^{56}$ erg. The derived field energies are reasonable compared with total energies of fields and particles in quasars and radio galaxies ($\sim 10^{60}$ erg).

For both sources acceleration of electrons takes place over a large region, and it is unlikely that this acceleration occurs simultaneously throughout that region. The maximum separation velocity resulting from impulsive injection of electrons at the centre of a magnetic dipolar field is $4.4c$. But for these two sources the injection cannot be truly impulsive. This offers the possibility of producing arbitrarily high separation velocities of double components. Suppose, for example, that acceleration of particles first occurs near the centre of the equivalent current loop of the extended dipolar field. Trains of electrons moving up the higher field lines of the extended field (Fig. 1) would have a head start on electrons moving up lower field lines. The difference in arrival times of the two electron trains ($t_2 - t_1$) would therefore be decreased and a higher apparent expansion velocity would be observed. Thus the apparent component separation velocity of $6c$ in 3C279 could occur if the injection of electrons at the centre of the extended dipolar field is not impulsive.

Observational predictions

It is difficult to imagine how the orientation of the dipole could change on a time scale shorter than that between successive flares. So I expect that all motions of radio source components should be along the same axis—the axis of the dipole projected onto the plane of the sky. In all subsequent outbursts the apparent motion of the components should be along an axis having the same position angle as the first observed event. This seems to be the case for BL Lac (ref. 4).

Second, since the distribution of electron pitch angles in the synchrotron emission regions (spots) is strongly peaked around zero, I expect a resultant circular polarisation of the

radio emission from the individual source components of the order of a few per cent. The direction of the magnetic field is predominantly toward the observer in one of the spots and away from the direction of the observer in second spot. So the sense of the circular polarisation should be opposite in the two components of the double source. In other words, the relative intensity of the two source components should be different by a few per cent when observed in opposite senses of circular polarisation.

Finally, since the burst of electrons from the central object could be an extended event in time, some sources might have the structure of a double jet with a rapid outward-moving brightening at the two opposite ends of the jets.

I thank F. W. Peterson, L. Woltjer, K. I. Kellermann, D. S. De Young and W. C. Saslaw for comments.

Intermittent momentum transport in a geophysical boundary layer

THE development of flow visualisation techniques^{1,2} has prompted a renewal of interest in investigating the dynamics of turbulent boundary layers. The discovery that turbulence is generated intermittently, in "bursts"³, near the wall, is of particular significance. It has also been found that the ejections and inrushes of fluid that accompany the bursts of turbulence generation are dominant contributors to the Reynolds stress⁴⁻⁶. These ejections and inrushes extend well into the flow. It follows that momentum transport in turbulent boundary layers is an intermittent process and that the intermittency is not confined to the region near the wall where most of the turbulence production takes place.

Can such laboratory results on turbulence structure be applied directly to boundary layers of geophysical scale? The potential importance of intermittence-related phenomena in large scale flows has been discussed by Mollo-Christensen⁷

and by Grass⁸. The work by Dorman and Mollo-Christensen⁸ also gives some direct evidence for intermittent momentum exchange in the atmospheric boundary layer.

For some time, a colleague and I have been investigating the turbulent structure of an estuarine, tidal flow and interpreting our results in terms of contemporary research on boundary layers⁹. The continuing analysis of our measurements has included a search for evidence of intermittency in this boundary layer of geophysical dimensions. We have found that the turbulent transport of momentum, or the Reynolds stress, is highly intermittent and that the observations are consistent with the results of wind tunnel and laboratory measurements made at lower Reynolds numbers.

The field experiments were carried out in the Choptank River estuary on Chesapeake Bay. Vertical and horizontal current velocities were sampled every 2 s for approximately two tidal cycles. The overall depth at the measuring station was 8–9 m and currents were recorded at various distances above bottom using a pivoted-vane current meter¹⁰. The maximum tidal flow was approximately 75 cm s^{-1} yielding Reynolds numbers based on depth of the order of 10^6 – 10^7 during most of the cycle. At these flow rates the sampling interval of 2 s allowed detection of turbulence structure with horizontal dimensions ~ 1 m. Turbulent fluctuations in the horizontal current in the direction of the mean flow (u')

FIG. 1 Time series of the correlation between horizontal (u') and vertical (w') current velocity fluctuations at 2.25 m above bottom showing intermittent, large contributions to the Reynolds stress. Decelerating flood tide (current 62 cm s⁻¹). Run 541-570. $\rho u'w'$ (8 min average) = 5.16. Six events in 7% of the time account for 54% of the measurement of Reynolds stress.

and in the vertical current (w') were obtained by calculating deviations from a third degree polynomial fit to the sampled currents. The velocity fluctuations (u' and w') were then

FIG. 2 Time series of the correlation between horizontal (u') and vertical (w') current velocity fluctuations at 1 m above bottom showing intermittent, large contributions to the Reynolds stress. Decelerating ebb tide (current 47 cm s⁻¹). Run 661-690A. $\rho u'w'$ (8 min average) = 1.98. Six events in 9% of the time account for 70% of the measurement of Reynolds stress.

correlated to yield the Reynolds stress component that defines the vertical transport of horizontal momentum, $\tau_{xz} = -\rho u'w'$, where ρ is the density of water. The averaging interval indicated by the bar over $u'w'$ was 8 min. The results presented here represent initial processing of data from 100 such intervals of 8 min taken during different phases of the tide.

Figures 1 and 2 show two typical intervals of 8 min in which individual values of $\rho u'w'$ are plotted against time. The Reynolds stress value is obtained from the average of these velocity correlations. Corrsin¹¹ has cautioned against referring to the individual products $\rho u'w'$ as the "instantaneous

Reynolds stress" but it is clear that there is intermittent structure in these 'events' which, when averaged, make up the Reynolds stress. Much of the final value of τ_{xz} is contributed by a relatively few, intermittent, highly correlated fluid motions. The UJs and DJs classify the kinds of events that transport the momentum—UJ signifies an upward jet of slower moving water ejected away from the bottom boundary into the main stream; DJ indicates a downward jet of faster moving water approaching the bottom. The percentage contributions of each of these events to the Reynolds stress value are shown. Table 1 summarises the relative contributions of events in different quadrants of the $u'w'$ plane to the Reynolds stress. These results are in good agreement with the laboratory data of Wallace, Eckelmann and Brodkey⁶, which were obtained from hot film measurements in an oil channel.

The frequency of momentum transporting events rather arbitrarily depends on the criteria used to define an event. Events in Figs 1 and 2 were simply taken as the six largest values of the products $u'w'$. If any value of $u'w'$ more than two standard deviations from the median is considered to be an event, the data treated so far indicate that events typically occur about every 25 s. This result may be compared with the wind tunnel data of Rao *et al.*¹². Their studies of the "bursting rate" as a function of R_θ (Reynolds number based on the momentum thickness θ) indicate that the period between events scales on the flow parameters of the outer part of the boundary layer, U and δ^* . (U is the mean flow velocity and δ^* is the displacement thickness.) Using the conclusions of Rao *et al.*¹² and typical values of U and δ^* from our data, the predicted period between events is about 35 s. The agreement of the observed and calculated frequency is close enough to indicate that we are dealing with the same kind of intermittent phenomena in the geophysical boundary layer.

Figure 3 consolidates data from 100 samples of 8 min of the type shown in Figs 1 and 2. The abscissa represents the percentage of the time occupied by individual products $u'w'$, selected on the basis of magnitude only, without regard to sign. The ordinate is the percentage contribution that these selected events make to the measurements of Reynolds stress. About 15% of the Reynolds stress is due to events occupying approximately 1% of the time, whereas some 60% of the stress is produced in only 10% of the time. If extrapolated slightly, this result is in good agreement with the wind tunnel observations of Willmarth and Lu⁵ who found that 99% of the stress value was contributed in 55% of the time.

FIG. 3 The degree to which intermittent, momentum transporting events contribute a disproportionate share to the Reynolds stress. IQ, Interquartile.

TABLE 1 Relative contributions of events in the $u'w'$ plane to Reynolds stress (%)

Distance off bottom	$u' < 0, w' > 0$	$u' > 0, w' < 0$	$u' < 0, w' < 0$	$u' > 0, w' > 0$
1 m	65 ± 3	67 ± 6	-15 ± 4	-15 ± 4
2.25 m	73 ± 8	65 ± 8	-17 ± 6	-20 ± 8
Wallace <i>et al.</i> ⁶	~ 68	~ 60	~ -15	~ -15

Our measurements in an estuarine tidal flow indicate that the intermittent phenomena observed in wind tunnel and laboratory boundary layers can be scaled up to dimensions of geophysical interest. It may well be that the intermittence of momentum transport is a prominent and characteristic feature of most geophysical boundary layers.

"Bursting" phenomena in the sea

INTEREST in the structure of turbulent boundary layers and in particular mechanisms responsible for the transfer of turbulent energy and generation of Reynolds stress has recently been stimulated by a series of laboratory flow visualisation experiments¹⁻⁵. These have indicated that Reynolds stress production is intermittent and associated with a sequence of motions known collectively as "bursting"³. Experimental evidence presented here suggests that similar motions can be readily identified in a geophysical boundary layer at length and time scales unattainable in the laboratory.

The observations reported here form part of a larger programme carried out between 1971 and 1973, in which systematic measurements of near bottom turbulence have been made in the Irish Sea. The primary objective of this study has been to determine by conventional means⁶⁻⁹ the frictional interaction between tidal currents and the sea bed and to extend previous observation^{6,9} of the turbulent structure of bottom boundary layers from estuarine and coastal waters to conditions more typical of circulations in the sea.

Measurements have been carried out at locations shown in Fig. 1, at which depths have varied between 10 and 60 m and maximum surface currents have been of the order of 1 ms^{-1} . The horizontal and vertical turbulent velocity fluctuations u and w have been measured at various heights in the bottom 2 m of the boundary layer using electromagnetic current meters¹⁰. These were mounted on a probe which was lowered to the seabed from the surface. Voltage analogues

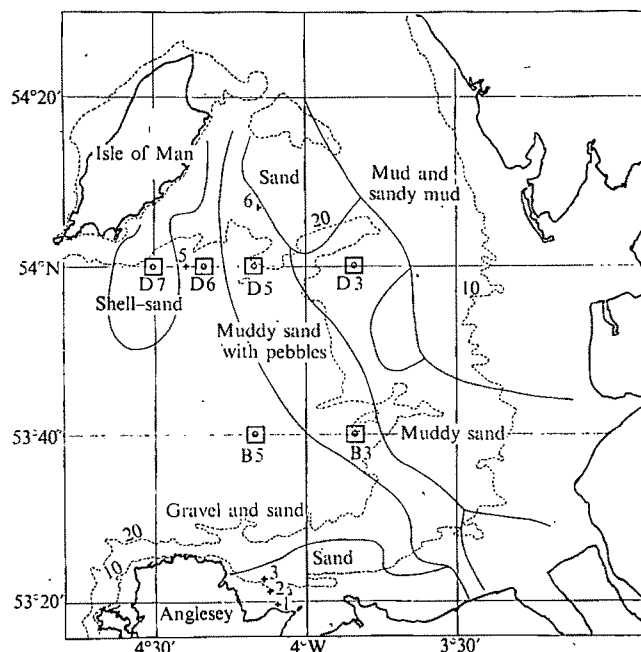

FIG. 1 Locations at which observations of bottom turbulence have been made in the Irish Sea between 1971 and 1973.

of the turbulent velocity components were transmitted to a ship at the surface by cable, recorded on magnetic tape and digitally on punched paper tape. It has been possible to measure simultaneously the contributions to the Reynolds stress ($-\rho u'w'$ where ρ is the fluid density) at two heights above the seabed over a wide range of flow conditions, depth and bottom sediments. Approximately 150 time series (10 min each) of u and w have been obtained, together with measurements of the velocity profile over the entire depth. Records have been replayed through low pass analogue filters into a data logger and digitised at intervals between 0.63 s and 0.08 s. The mean, standard deviation, skewness and kurtosis for each record were calculated before spectral analysis using standard digital methods. The turbulent spectra of u and w and the Reynolds stress cospectrum, corrected for the frequency response of the current meters and filters, non-simultaneous sampling and sensor misalignment, have been computed and are being used to determine those scales of motion contributing to the Reynolds stress.

Reports of bursting phenomena in laboratory experiments¹⁻⁵ have prompted us to examine our records for similar mechanisms. Figures 2 and 3, showing reconstructed analogues of u , w and uw from two different locations, indicate the intermittent nature of the stress input to the boundary layer by a pronounced asymmetry of the uw trace. Record 2/14, made with a sensor of diameter 10 cm and a time constant of approximately 1.0 s, has fewer high frequency components than record 11/4/2, obtained with a sensor of diameter 5 cm having an overall time constant of 0.1 s.

Inspection of the signs and magnitudes of u and w in Fig. 2 identifies the large values in the uw record as belonging to the bursting process and following the usual convention⁵, these events can be classified as follows:

- 1) $u < 0, w > 0, uw < 0$; an ejection of fluid away from the boundary.
- 2) $u > 0, w < 0, uw < 0$; a sweep or inrush of fluid toward the boundary.
- 3) $u > 0, w > 0, uw > 0$; a weak outward interaction of fluid from the boundary.
- 4) $u < 0, w < 0, uw > 0$; a weak inward interaction of fluid toward the boundary.

In particular those terms contributing to the ejection and

FIG. 2 Bottom turbulence record 2/14, station 2, depth of water 15 m. Analogues of u , w and uw at a height of 1 m above the seabed in a mean current of 22 cm s^{-1} and a Reynolds stress of $2.69 \text{ dynes cm}^{-2}$, showing ejection and sweep phases.

sweep phases have much larger amplitudes than the interaction processes. Comparison of these records with similar laboratory investigations² suggests that the large amplitude events are ejections and sweeps, with an ejection ($w > 0$) preceded by a deceleration of the horizontal flow and a sweep ($w < 0$) occurring after an acceleration.

The distributions of u , w and uw and their departure from gaussian behaviour have been examined in a number of records. The asymmetry of the uw analogue as a result of ejections and sweeps and the net positive input of Reynolds stress, is characterised by a negative skewness of its distribution around the mean. From the distribution of uw in record 2/14 (Fig. 4) it has been possible to determine the contribution of these events to the Reynolds stress. This single record illustrates that events occurring outside -3 standard deviations from the zero stress level contribute as much as 31% in only 3% of the time and events outside -2 standard deviations make a contribution of 57% in 7% of the time. This evidence supports the view¹ that, depend-

FIG. 3 Bottom turbulence record 11/4/2, station D6, depth of water 40 m. ing on Reynolds Number, as much as 70% of the Reynolds stress may be derived from ejections alone. More recent work⁵ has confirmed that both ejection and sweep motions are more intense than interactions and that in the region of maximum Reynolds stress in a bounded shear flow, ejections are about $1/3$ more intense than sweeps, existing for 20% less time. The duration of ejections and sweeps from our records is of the order of 5 to 10 s with periods between events typically 20 to 100 s. These periods seem to correspond with observed maxima in the Reynolds stress cospectrum⁶.

The implications of bursting phenomena in this example of a naturally occurring boundary layer and their influence on the shear stress at the seabed are not clearly understood. How-

FIG. 4 Distribution of uw in record 2/14 with respect to the mean (upper scale) and zero Reynolds stress (lower scale), showing percentage contributions to uw . Continuous curve is the Gaussian distribution for the same sample and standard deviation. 650 samples; mean $-2.62 \text{ cm}^2 \text{ s}^{-2}$; standard deviation $7.10 \text{ cm}^2 \text{ s}^{-2}$; skewness -1.92 ; kurtosis 9.27 . Percentage contributions to Reynolds stress marked by arrows.

ever, these observations do indicate that the generation of turbulence and Reynolds stress is intermittent and that it is possible to extend the scales of motion involved from laboratory to geophysical proportions.

Experiment to measure the antimatter content of the Tunguska Meteor

ON the morning of June 30, 1908 a meteor caused great damage in the region of the isolated trading station Vanovara in Siberia, Russia. Investigations of this meteor, called the Tunguska Meteor, have been described by Krinov¹. Light from the meteor was visible even in a sunlit, cloudless sky. There was an explosive wave, with an energy between 3 and 5×10^{23} erg², blowing down trees over an area of approximately 2,000 km². Thermal energy, estimated to be

TABLE 1 Average chemical composition of continental crust weight %

Magnesium	1.9
Titanium	0.5
Phosphorus	0.1
Manganese	<0.1

between 1 and 2×10^{23} erg, caused fires and seared trees up to 18 km from the centre of the blast. But it appears as though the meteor never reached the ground, for no crater was formed, nor have any fragments been found which can be positively identified as part of the meteor.

Several explanations have been discussed by Krinov¹. Cowan, Atluric and Libby have suggested that it was an antimatter meteor³ and Jackson and Ryan have postulated that it was a black hole⁴.

Cowan *et al.* suggested that if the Tunguska Meteor were a rock of antimatter, nuclear processes associated with the annihilation of the meteor would have increased the amount of ¹⁴C in the atmosphere. Subsequent assimilation of the ¹⁴C by trees might then be detectable. Their analysis of a tree that had been growing in Arizona in 1909 AD showed a smaller increase in the ¹⁴C content than they had predicted. The significance of this was difficult to interpret because of what seemed to be random yearly variations of ¹⁴C in the local atmosphere. Here I again examine the hypothesis of an antimatter meteor, to ascertain whether other experimental tests can be carried out.

Any event involving nuclear processes should produce radioactive nuclei. Of special interest is the electromagnetic cascade shower. This is produced in air by the decay into γ rays of the π^0 s which are produced when antimatter nuclei annihilate. When an electromagnetic cascade shower containing a wide spectrum of γ rays strikes the ground, radioactive nuclei are produced as a result of many different photonuclear processes.

The major constituents of rock and soil are oxygen, silicon and aluminium with smaller amounts of iron, calcium, potassium, magnesium, phosphorous and sodium, in the amounts given in Table 1 (see ref. 5).

To determine which radioactive products might be produced, the reactions (γ, p), (γ, n), (γ, d), and ($\gamma, 2n$) on the various isotopes of the elements listed in Table 1 have been considered. Only a few of these reactions (listed in Table 2) produce nuclei which are sufficiently long lived to be detected now approximately 2×10^9 s after the event.

The reactions which produce ²⁶Al have been given special consideration for two reasons. First, silicon, and to some extent aluminium, are abundant elements in rock (Table 1). Second, ²⁶Al decays predominantly by emitting a positron, whereas ³⁹Ar decays by emitting a β^- ray, and ⁵³Mn by

electron capture. The decay signature of a positron emitter, with the accompanying annihilation radiation, allows the design of systems which will more readily discriminate against background and thus measure smaller total activities.

An experiment to detect the antimatter component of the Tunguska Meteor is thus conceptually simple. The ²⁶Al content of rocks or soil is measured as a function of the distance from the centre of the explosion. The highest concentration of ²⁶Al should be found near the centre. In order to assess the technical feasibility of the experiment, however, the production of ²⁶Al must be examined in more detail.

The number of ²⁶Al atoms, N_{26} , created in the soil and rock by the flux of γ rays is given by the expression

$$N_{26} = \sum_i \frac{A_0}{A_i} f_i \int \frac{dN}{dE} \sigma_i(E) dE \quad (1)$$

where A_0 is Avogadro's constant = 6.02×10^{23} mol⁻¹, A_i is the atomic weight of the nucleus; f_i is the fraction by weight of the nucleus; $\sigma_i(E)$ is the cross section for production for ²⁶Al as a function of photon energy, E , and dN is the number of photons cm⁻² with energy between E and $E + dE$. For the problem under consideration here, equation (1) contains only two terms, corresponding to the nuclei of ²⁷Al and ²⁸Si.

An accurate calculation of the production of ²⁶Al is not possible because of uncertainties in both the incident flux of γ rays and the production cross section of ²⁶Al. Some estimate of these quantities can, however, be made. The γ -ray flux may be estimated in the following way. When a proton and antiproton annihilate, an average of four charged and two neutral pions are produced⁶. Thus about half of the available energy goes into the rest mass of pions and the remainder goes into kinetic energy. Each neutral pion decays into two γ rays which initiate an electromagnetic cascade shower.

The energy density received at the ground is reduced by both the solid angle and absorption in the air. The explosion has been estimated to have occurred between 5 and 6 km up in the atmosphere³. The height of the meteor site is approximately 300 m. At a distance of 5 km, the solid angle subtended by each square centimeter of the ground is 3×10^{-13} sr. The air mass, calculated by using a scale height of 8.4 km and integrating from 0.3 to 5.3 km, is 430 g cm⁻². The energy absorption coefficient of an electromagnetic cascade shower in air is assumed to be the same as that measured for water, that is 0.013 cm² g⁻¹ (ref. 7). This means that approximately 0.37% of the initial energy is transmitted through the air to the ground. The total energy, assumed to be 5×10^{23} erg, or 3×10^{20} MeV, is reduced by a factor of 6 because only a sixth of the energy is converted into γ rays, and by an additional factor of approximately 10^{15} resulting from a combination of the solid angle and absorption. Thus the energy flux at ground level is of the order of 5×10^{13} MeV cm⁻².

The energy spectrum of photons in the cascade shower is uncertain. Because of the kinetic energy of the π^0 s, the initial decay gammas will have a rather broad energy distribution centred at 68 MeV. Processes such as pair production and Compton scattering with subsequent bremsstrahlung by the pair-produced electrons, will further degrade the photon energy spectrum. On the other hand, lower energy photons are more strongly absorbed by the Compton process. (Photoelectric interactions are negligible at the energies considered here.)

Most γ rays produced by cosmic rays and observed in the atmosphere seem to come from π^0 production near the top of the atmosphere⁸. Thus, because the physical process of absorption and creation are similar, the spectrum of the flux induced by the Tunguska Meteor might be expected to be similar to that produced by cosmic rays traversing the same thickness of atmosphere.

If the change in radioactivity is to be detected, the burst of radiation at the Tunguska site must be appreciable when compared with the total cosmic-ray flux integrated over the average lifetime of ^{26}Al . Two estimates of the integrated cosmic-ray flux lead to similar answers. The average radiation background resulting from cosmic rays at sea level is approximately 50 mR yr^{-1} . This implies a total dose of $2.4 \times 10^8 \text{ MeV cm}^{-2} \text{ yr}^{-1}$. The γ -ray flux integrated for energies of about 30 MeV and extrapolated to sea level is approximately $3 \times 10^{-2} \text{ cm}^{-2} \text{ s}^{-1}$ (ref. 8). The integrated energy in this flux yields an energy of $3 \times 10^8 \text{ MeV cm}^{-2} \text{ yr}^{-1}$. The average lifetime of ^{26}Al is $1.07 \times 10^6 \text{ yr}$ and so the additional flux calculated to have been produced by the Tunguska Meteor represents a 15% increase in the total dose received over the past million years.

TABLE 2 Long-lived isotopes

Parent Nucleus	Reaction	Daughter Nucleus	Half-life (yr)
^{27}Al	γ, n	^{26}Al	7.4×10^5
^{28}Si	γ, d	^{26}Al	7.4×10^5
^{41}K	γ, d	^{39}Ar	269
^{54}Fe	γ, p	^{53}Mn	1.1×10^7
^{55}Mn	$\gamma, 2n$	^{53}Mn	1.1×10^7

To obtain the effective production rate, the γ -ray spectrum must be integrated with the cross section as shown in equation (1). The energy spectrum of γ rays in the atmosphere has been measured by Thompson⁸. Very approximately, the energy spectrum of γ rays at a depth of 500 g cm^{-2} can be fit by a power law of the form

$$\frac{dN}{dE} \propto E^{-1.6} \quad (2)$$

The cross sections for the production of ^{26}Al in the ground state by either of the two reactions listed in Table 2 have not been measured. The cross section for $^{27}\text{Al}(\gamma, n)^{26}\text{Al}^*$, where ^{26}Al is the 0.239 MeV first excited state ($\tau_{1/2} = 6 \text{ s}$), has been measured for photon energies up to 62 MeV (ref. 9). If the ^{26}Al is initially formed in a highly excited state, the probability of radioactive decay to the short-lived first excited states with spin and parity of 0^+ should be about the same as for decay to the long lived ground state which has spin and parity of 5^+ . For the predicted spectrum, equation (2), and the measured cross section, the integral evaluated by numerical methods is

$$\int \frac{dN}{dE} \cdot \sigma(E) dE = 3 \times 10^{-15} \text{ photons/nucleus.}$$

Values of the cross section for the second reaction $^{28}\text{Si}(\gamma, d)^{26}\text{Al}$ have not been reported. The cross section for $^{32}\text{S}(\gamma, d)^{30}\text{P}$ has, however, been measured from threshold to 80 MeV (ref. 10). If this measured cross section is used, a numerical value of the integral is obtained.

$$\int \frac{dN}{dE} \cdot \sigma(E) dE = 2 \times 10^{-15} \text{ photons/nucleus}$$

In the following discussion a value of 2×10^{-15} photons/nucleus is adopted for both reactions.

The amounts by weight of silicon and aluminium in average rock are 29 and 8%, respectively (Table 1). The production of ^{26}Al in rock at the centre of the meteor site, is therefore estimated to be 4×10^8 atoms per kg of rock. With an ^{26}Al half life of 7.4×10^5 years, this corresponds to an induced specific activity of approximately $10^{-2} \text{ d.p.m. kg}^{-1} \text{ rock}$.

Tanaka *et al.*¹¹ have attempted to measure low levels of activity due to ^{26}Al found in deeply buried rock. They report an upper limit of $10^{-2} \text{ d.p.m. kg}^{-1} \text{ rock}$, a value

which is approximately the size of the predicted effect.

Most detection systems for measuring very low levels of positron emission consist, at least in part, of opposing NaI(Tl) crystals which detect in coincidence the two 0.511 MeV γ rays from the annihilation of the positron^{12,13}. For such a system, and for a given observing time, the sensitivity, S , is defined as the ability of a detector to measure activity, and

$$S \propto \frac{\epsilon N}{\sqrt{B}} \quad (3)$$

where ϵ is the detector efficiency, N is the number of nuclei that can be placed in the detector and B is the background rate. Tanaka *et al.*¹¹ suggested that the sensitivity of their instrument could be improved if larger detection crystals were used and if purer and more concentrated samples were obtained. These ideas suggest that considerable increase in sensitivity should be possible. For example, NaI(Tl) crystals are available with an area up to 100 times that of detectors used by Tanaka *et al.*¹² and Roedel¹³, and three times as thick. Even if the background increases linearly with the volume of detector, sensitivity would be increased by a factor of six because more sample could be placed between the crystals. In addition, such large NaI(Tl) would increase the photo-fraction efficiency and thus the sensitivity.

The use of pure aluminium, rather than the Al_2O_3 used by Tanaka *et al.* would increase the reported sensitivity by a factor of about two because more Al nuclei could be introduced into the same volume.

It might be possible to select rocks, such as quartz or limestone; which are largely free from aluminium. The extraction of aluminium from such rock samples would increase the specific activity of ^{26}Al in the sample by more than an order of magnitude.

In addition to the ideas discussed above, a promising method of reducing the background in β^+ counting systems, by observing the positron in coincidence with the annihilation γ rays, has been developed¹⁴. We have recently developed a simple version of such a system which yields a gain in sensitivity of a factor of two over an equivalent two- γ -ray detector system.

With the technical improvements in detectors that seem feasible, a system with an increase in sensitivity of almost two orders of magnitude could be planned. This would allow the detection of an increase of only a few % in ^{26}Al content. The proposed experiment could then be readily carried out.

I acknowledge the impetus of a lecture by Professor C. L. Cowan. I also profited greatly from conversations with many colleagues and especially C. L. Cowan, C. J. Crannell, C. Fichtel, J. M. Finn and D. J. Thompson. This work was supported in part by a National Science Foundation grant.

Comets, solar wind and the D/H ratio

I wish to speculate on the consequences of considering together two astronomical observations. First, the Sun emits a matter flux of $\sim 10^{12}$ g s⁻¹ in the form of a solar wind¹. The chemical composition seems to be rather similar to the solar photospheric composition². So it incorporates a fractional mass of about 1% of atoms which are good candidates for grain formation (ices as CH₄, NH₃, H₂O; dusts as silicates and irons). Thus a flux of $\sim 10^{10}$ g s⁻¹ of condensable matter flows away in the remote parts of the Solar System.

Second, the number of newly arriving comets (of long period) is about one a year with a mean mass of $\sim 10^{18}$ g (ref. 3) and a comet can be pictured plausibly as a conglomerate of ices and dusts⁴. Thus a mean flux of $\sim 3 \times 10^{10}$ g⁻¹ of cometary matter flows inwards from the remote part of the Solar System.

These fluxes seem to agree within one order of magnitude or better. I assume that this is not a pure coincidence.

The process could be pictured in the following way. The ionised atoms of the solar wind follow the laminar flow lines until they reach a boundary where, presumably because of interaction with the interstellar magnetic field, the wind becomes turbulent. There, they are progressively decelerated, recombine, form molecules and eventually grains of increasing sizes. (Although very little is known about how the grains are formed, observations of interstellar matter indicate that the process must be very efficient; otherwise, how could the striking depletion of the refractory elements in the interstellar gas^{5,6} be explained?) The grains are carried away by the turbulent gas and collide with each others. Dust and ices will mix and stick together, thus generating the embryos of comets.

These objects are subjected to two forces: the inward gravitational pull of the Sun and the drag force of the turbulent motions with its residual outward component. As the size of the object increases the second force becomes gradually weaker than the first. The outward motion is decelerated until the object start moving toward the Sun. A comet is born.

So we have a picture of a stationary cloud in which matter is fed in through the solar wind, and out through conglomerates of ices and dusts. The cloud has, in the past, grown to a stage at which the feeding out just compensates the feeding in, thereby explaining the rough equality between the two fluxes.

Before this model becomes credible several points will have to be clarified, several quantitative estimates (of the location and properties of the cloud, of the accretion rate in the cloud and so on) will have to be carried out and several 'tests' will have to be 'passed.' For example, the observed distribution of kinetic energies, of ellipticities and of orbital inclinations of the comets should find a reasonable explanation within the frame of the model.

The orbital planes of the long-period comets do not seem to raise any problem: they are tilted in all directions as expected from the plausible spherical symmetry of the solar

wind. The eccentricities would be assigned to such effects as the random drag velocities of the cells.

But at present, instead of pushing this discussion further, I stress the importance of measuring the D/H ratio in cometary matter by showing its relevance to the problem of the origin of the comets.

The D/H ratio in interstellar space is 1.5×10^{-5} (ref. 7). In oceanic and meteoritic water, on the other hand, the ratio is 1.4×10^{-4} ; the increase is probably due to molecular exchange reaction at the time of formation of the water⁸. In the solar wind D/H $< 3 \times 10^{-6}$, (ref. 9) compatible with the fact that the Sun burned its deuterium in its early days.

Clearly this model of comet formation would predict essentially no D (D/H $\ll 10^{-5}$). If, on the other hand, the comets were made early in the history of the Solar System, by matter left over from the protosolar condensation (the Oort's cloud), depending on their formation temperature we should have in the various cometary molecules a D/H ratio of anything from 10^{-5} to 10^{-4} and possibly even more (see tables in ref. 10). Measurements of DCN/HCN, CH₃D/CH₄, OD/OH in comets would be of the utmost importance.

Evolution of dense galactic nuclei through dwarf star collisions

STELLAR collisions are important in dense galactic nuclei¹⁻³. QSOs, N galaxies and Seyfert galaxies release energy on similar short time scales⁴⁻⁷ but detailed models of stellar collisions have been limited so far to collisions between two main sequence stars, with the conclusion that for an initial relative velocity $V_{rel} \lesssim 10^3$ km s⁻¹, and small impact parameter, coalescence follows. At $V_{rel} \sim 5,000$ km s⁻¹ two colliding main sequence stars are largely disrupted and a non-negligible amount of relativistic particles is formed⁸. Here we draw attention to the fact that a very important type of collision in dense galactic nuclei is one in which a white dwarf (WD) is involved.

Van den Bergh⁹ has pointed out that most collisions in the nuclei of 'normal' galaxies such as M32 involve two dwarf M stars or one M dwarf (dM) and one late-type giant. The reason is the high abundance of dM stars and the large cross section of giants. The evolution of a nucleus therefore depends on the outcome of WD-WD, WD-dM, dM-dM and dM-giant collisions. We neglect dM-giant collisions because most of them will occur in the highly rarified atmosphere of a giant and consequently will have a very small effect. For simplicity we discuss only dM-WD collisions with impact parameter p smaller than $0.75R$, where R is the radius of the red dwarf.

The escape velocity of a white dwarf varies from 2,500 km s⁻¹ for a WD with $M = 0.25M_{\odot}$ to 16×10^3 km s⁻¹ for a WD with $M = 1.25M_{\odot}$; it is ~ 600 km s⁻¹ for late-type main sequence stars. Consequently, the WD-dM collision of low V_{rel} is governed by the white dwarf gravitational field. As the initial relative velocity of the colliding stars increases (the stellar cluster becomes denser) the dynamics of the collision are governed more and more by the initial relative velocity.

We consider a typical collision between a WD of $1M_{\odot}$ and a dM star of $0.2M_{\odot}$ at $V_{rel} \sim 10^4$ km s⁻¹ and impact parameter $p < 0.75 R$. Since this velocity is greater than the speed of sound in the dM star the effect of gravity on the structure of the red dwarf is small. Further, the change in the velocity of the WD during the collision can be neglected. The time spent by the WD inside the dM star is 10 to 30 s which is more than an order of magnitude smaller than the dynamical time scale of the dM star. So only a small amount of mass can be accreted onto the WD from the dM star. Hoyle and Lyttleton⁹ found that the "capture radius" σ of a star of mass M moving at constant velocity V through an infinite medium is $\sigma = 2GM/V^2$, where G is the gravitational constant. In our example $\sigma \sim 3 \times 10^8$ cm and the density scale height h_p for the dM is $\sim 10^9$ cm for $r \lesssim 0.75R$. So the assumption of an infinite medium is valid. But σ is about $\frac{1}{2}$ the radius of the WD and Hoyle and Lyttleton's theory is not valid for $\sigma < R_{WD}$. A plausible assumption is that $\sigma \sim R_{WD}$ and the total mass accreted by the WD is then $(1 \text{ to } 3) \times 10^{-4}M_{\odot}$. All other parameters being equal, the total mass accreted by a WD will increase for white dwarfs with lower mass and larger radius.

Most of the accreted material is rich in hydrogen because nuclear timescales in a $0.2M_{\odot}$ star are longer than the Hubble time. When the mass accreted exceeds $\sim 10^{-5}M_{\odot}$ nuclear energy generation becomes violent enough to drive a thermal runaway¹⁰⁻¹³ typical of novae. The fate of the runaway depends on the WD initial temperature T (ref. 13). At $T \lesssim 3 \times 10^7$ K the runaway ends in an explosion whereas in hot white dwarfs with $T \gtrsim 4 \times 10^7$ K the energy generation rises until a steady state is reached. At some later time the hydrogen is exhausted and the nuclear reaction decays. In models calculated by Saslaw²³ 10^{47} to 10^{48} erg is released. It will be shown later that plausible models of galactic nuclei give time intervals, between subsequent collisions, of 10^6 to 10^7 yr for each white dwarf. Since the cooling time of white dwarfs is $\sim 10^9$ yr most white dwarfs have $T > 4 \times 10^7$ K and the second process mentioned above occurs. The typical white dwarf thus produces a series of novae at a rate of one per 10^6 to 10^7 yr.

Similar arguments concerning collision energetics show that most dM-dM collisions lead to substantial mass loss if $V_{rel} \sim 10^4$ km s⁻¹, and that the rarer head-on collisions disrupt both stars. Thus, dM-dM collisions transform the dM stars into white dwarfs made of unburnt nuclear material.

In the case of WD-WD collisions a simple estimate yields a collision cross section $\sigma_{WD-WD} \sim (500)^{-1} \sigma_{WD-dM}$ for $V_{rel} \sim 10^4$ km s⁻¹. At $V_{rel} \sim 10^4$ km s⁻¹ the most probable outcome of a collision of two white dwarfs of $1M_{\odot}$ is one white dwarf with a total mass in the range 1 to $2M_{\odot}$. Such a velocity is too low to be energetically capable of disrupting the stars. The WD-WD collisions differ from the WD-dM collisions in two respects. First, WD-WD collisions raise the mass of the remaining white dwarf more than a WD-dM collision and may bring the final product to a mass above the Chandrasekhar limit. Second, the frequency of WD-WD collisions is two or three orders of magnitude smaller than the frequency of dM-WD collisions. This will probably give rise to supernova explosions of a certain frequency.

The evolution of a dense galactic nucleus depends on the transformations between the various stellar species due to stellar collisions. We consider a highly simplified model of a

spherical galactic nucleus of radius R made up of N_{dM} dM stars of $0.2M_{\odot}$ and radius $r_{dM} \sim 0.2R_{\odot}$, and N_{WD} white dwarfs of $1M_{\odot}$ and radius $r_{WD} \sim 8 \times 10^{-3}R_{\odot}$.

We assume that the average velocity can be obtained from the Virial Theorem. The mean free path of a white dwarf for collision with a dM star is

$$\lambda_{WD-dM} \sim \frac{R^3}{N_{dM} r_{dM}^2}$$

and similar expressions hold for λ_{dM-dM} and λ_{WD-WD} . The total number of WD-dM collisions per unit time, n_{WD-dM} is given by

$$n_{WD-dM} \sim 3 \times 10^{18} N_{WD} N_{dM} M_i^{1/2} R^{-7/2} \text{ s}^{-1}$$

where M_i is the total mass of the nucleus and we assume roughly equal velocities for all stars.

We consider the following ranges for the various parameters: $N_{dM} = (0.2 \text{ to } 20) \times 10^{10}$, $N_{WD} = (0.2 \text{ to } 20) \times 10^{10}$ and $R = (0.25 \text{ to } 1.0)$ pc (see refs 14 and 15) in which the parameters of NGC4151 are discussed). Two fairly extreme cases are $R = 0.25$ pc, $N_{dM} = 2 \times 10^{10}$ and $N_{WD} = 2 \times 10^{11}$; and $R = (0.25 \text{ to } 1.0)$ pc (see refs 14 and 15 in which the typical energy releases for novae are $\sim 10^{47}$ erg then $\sim 10^{48}$ erg s⁻¹ and $\sim 10^{42}$ erg s⁻¹ are released in these two models. The supernova rate varies from 10^3 yr⁻¹ to 10^{-3} yr, respectively. But most of the contribution to the total energy release does not come from the supernovae.

Eventually, the number of dM stars decreases and with it the total energy output. If one starts with $N_{dM} \sim 2 \times 10^{11}$ (all of $\sim 0.2M_{\odot}$) and $N_{WD} \sim 2 \times 10^{10}$ (all of about $1M_{\odot}$) the energy output matches that of bright QSOs. A reduction of N_{dM} by a factor of 10 (which is caused by dM-dM collisions over a timescale of 10^6 yr) brings to total energy output to the range of N-type galaxies. Still another reduction by a factor of 10 (over a timescale of 10^8 yr) reduces the energy output to the range of Seyfert galaxy nuclei. Finally, in about 10^9 yr N_{dM} drops to $\sim 2 \times 10^9$ and the energy output due to collisions falls to about 10^{40} erg s⁻¹. The timescale for the change in N_{dM} is easily obtained from the collision frequency and average mass loss per collision. Clearly, the timescale for changes becomes longer as the number of dM stars decreases. At the same time the principal energy source changes as well. At early stages it is predominantly the dM-dM collisions whereas later it becomes the WD-WD collisions and finally the WD-dM collisions.

So it seems that, assuming about 10^{47} erg to be released in a nova caused by a WD-dM collision, we find that stellar collisions in dense galactic nuclei can explain the basic energetics of QSOs, N-type galaxies, Seyfert galaxy nuclei and the central regions of bright elliptical galaxies, as well as their evolutionary connection and sequence.

M.M.S. thanks Dr Sidney van den Bergh for a discussion about stellar collisions in galactic nuclei.

Observation of $O^+(^2P^o-^2D^o)\lambda 7,319\text{\AA}$ emissions in the twilight and night airglow

TEN years ago Dalgarno and McElroy¹ suggested that the $^2P^o \rightarrow ^2D^o$ transition of the atomic oxygen ion would be produced in the upper atmosphere through the simultaneous photoionisation and excitation of atomic oxygen atoms by solar ultraviolet radiation.

The photoionisation cross section calculations of Dalgarno, Henry and Stewart² indicate that approximately 25% of the photons absorbed by atomic oxygen below 663 Å will produce O^+ ions in the metastable $^2P^o$ state. Using these cross sections, Dalgarno and McElroy³ computed dayglow emission rates and later extended their calculations to the twilight situation⁴. This excitation mechanism has been observed in the laboratory in photoelectron spectroscopy measurements by Jonathan *et al.*⁵ who found an efficiency of ~22% for producing the $^2P^o$ state at 584 Å. Thus, both theory and experiment indicate that photoionisation excitation of $O^+(^2P^o)$ is an efficient process and should produce an observable $^2P^o \rightarrow ^2D^o$ airglow feature as predicted in the work of Dalgarno and McElroy.

As yet no observations of this transition in the airglow have been reported.

Fig. 1 Upper spectrum: average of the observations obtained during evening twilight for solar depression angles in the range 8.5° to 10°. Lower spectrum: evening scans between 10° and 12°. Points shown represent three-point running averages. a, OH (8-3) $P_1(2)$ feature; b, $O II (^2P^o-^2D^o)$ feature. August 26-30, 1973.

Fig. 2 Observed night airglow spectrum. a, b as Fig. 1. August 26-30, 1973.

This work reports twilight and nightglow observations of the $^2P^o_{1/2, 3/2} \rightarrow ^2D^o_{5/2}$ line group at $\lambda 7,319\text{ Å}$. Assuming that the upper J levels are populated according to their statistical weights, then the $^2P^o_{3/2} \rightarrow ^2D^o_{5/2}$ $\lambda 7,319.4\text{ Å}$ line will be stronger by approximately a factor of three or greater than the $^2P^o_{1/2} \rightarrow ^2D^o_{5/2}$ $\lambda 7,318.6\text{ Å}$ line. The mean wavelength for the two lines is then approximately $7,319.2\text{ Å}$. The observations were made in the zenith at Table Mountain which is ~70 km NNE of Los Angeles and 2,300 m above sea level. The sky conditions there are excellent for airglow observations. A 0.3 m $f/5.3$ spectrometer with a 1,200 lines mm^{-1} grating blazed at 5,000 Å was used to disperse the spectrum. The entrance and exit slit sizes were $55\mu\text{m} \times 2\text{ cm}$ and $65\mu\text{m} \times 2\text{ cm}$ respectively, which resulted in a spectral resolution of approximately 2.3 Å. Any second order contribution was reduced using two interference filters, one in reflection and one in transmission. The radiation was detected with an EMI 9558 QB photomultiplier with an S-20 photocathode cooled to -20°C . Using magnetic and optical lenses, only the central portion of the photocathode was effective, resulting in a dark counting rate of 1-2 s^{-1} . The observations were obtained during the period of new Moon, August 26-30, 1973. The wavelength region 7,314 to 7,322 Å was scanned repeatedly at 5 Å min^{-1} during twilight and accumulations for 4 s were recorded. The nightglow measurements were obtained at slower scanning speeds and longer integration periods.

The Rayleigh scattering component of the twilight was estimated by least-squares fitting and extrapolation of the signals observed for solar depression angles between 4° and 8°. This contribution was subtracted from the observed signals, with the dark count signal, to give the spectra shown in Fig. 1.

It is clear from Fig. 1 that the $O^+(^2P^o-^2D^o)$ $\lambda 7,319\text{ Å}$ feature is present in the twilight spectrum and decreases in intensity as the solar depression angle increases, in qualitative agreement with the variation expected for excitation by solar ultraviolet radiation. The absolute intensity of the O^+ feature is greater than that predicted by Dalgarno and McElroy. This may be due to both experimental error and differences between the actual and model atmosphere and the absorption cross sections used in the calculations⁴. The nearby OH(8-3) $P_1(2)$ line⁶ is also apparent and seen to diminish in brightness as evening twilight progresses approximately as predicted by the model of Shimizaki and Laird⁷.

In the nightglow, where direct solar excitation is absent, the O^+ feature is still found (Fig. 2). We suggest that extreme ultraviolet photoionisation excitation is also responsible for

at least part of this nightglow feature. Both He I $\lambda 584 \text{ \AA}$ and He II $\lambda 303 \text{ \AA}$ emissions will be incident on the night-time upper atmosphere, arising from resonance scattering of the solar helium lines, the former by interplanetary and exospheric He and the latter by plasmaspheric He^+ ions⁸⁻¹². It is difficult to estimate the nightglow $\lambda 7,319 \text{ \AA}$ intensity that would be produced by this excitation mechanism since the background ultraviolet radiation can show considerable variation. The He I $\lambda 584 \text{ \AA}$ may exhibit a seasonal variation due to the non-uniform interplanetary density distribution¹³ and plasmaspheric He^+ concentrations, and the resulting $\lambda 303 \text{ \AA}$ flux, can also show large fluctuations.

We are grateful for the hospitality extended to us at the Table Mountain site by the staff of the Jet Propulsion Laboratory, California Institute of Technology.

An organic 'metal'?

LITTLE¹ has proposed a mechanism by which an electron-electron (e-e) interaction in certain organic polymers and macromolecules might result in a high superconducting transition temperature. This e-e mechanism requires a combination of two systems consisting of a conducting or semiconducting polymeric compound forming a spine, with highly polarisable side chains attached to the spine. According to Little, the addition of such side chains can increase the e-e attraction in the spine to the point where it becomes energetically favourable to enter the superconducting state. This e-e mechanism of superconductivity has led to lively discussions, primarily concerned with superconductivity in quasi one and two-dimensional systems^{2,3}, and the magnitude of the e-e attraction^{4,5}. It has been shown theoretically³ that, depending on the nature of the interaction between the electrons, a quasi one-dimensional system may exist in different states: metallic, dielectric, antiferromagnetic and superconducting. It has also been shown experimentally that the organic charge transfer salt N-methyl-pehnazinium tetracyanoquinodimethan has 'metallic' properties at temperatures above 200 K with a continuous transition to a small-band-gap insulator below 200 K (ref. 6).

We have been investigating a number of organic compounds in which the e-e interaction is expected to be large. Here we wish to report one of a potentially large class of organic compounds which has 'metallic' electrical properties over a large temperature range. This compound, we believe, is an intercalation compound consisting of a triphenylmethane dye (malachite green) and graphite. Graphite in which the bonding between the carbon layers is weak has been known to form intercalation compounds with alkali metals⁷, acids⁸, halogens⁹ and metal chlorides⁹. The intercalation compounds of K, Rb, and Cs with graphite have been shown to have superconducting transition temperatures of 0.55, 0.155, and 0.135 K respectively¹⁰. (Metallic conduction has also been observed in the metal chloride intercalation compounds⁹.) In the complex described here the graphite, which is a highly conjugated layer compound, acts as the semiconducting spine or sheet, and the dye, complexed to the graphite, is similar to the polarisable side chains of Little's model. The chemical structure of the malachite green dye molecule, and two of its resonance structures is shown in Fig. 1.

This complex, and others of the same general class, is prepared as follows: very high purity samples, 98-99% pure, of malachite green dye and powdered graphite are thoroughly mixed in a mass ratio of three parts of dye to one part of graphite. The powder mixture is heated to the melting point of the dye. The melting point of the dye depends on the purity of the sample and is, in general, greater than 250° C. When the entire sample is in a soft to semi-molten state, the complex is allowed to cool to room temperature when it becomes a hard, black vitreous solid.

Powder X-ray diffraction studies of this compound have shown a broad diffraction peak equivalent to a lattice spacing of 6 Å which may indicate the formation of an intercalation complex. Probes for resistance measurements were usually inserted into the complex while in the soft state, at 150-200° C and the complex was allowed to cool. On cooling, the probes became tightly bound to the sample. Resistance measurements were usually made with copper probes, 1 cm long, separated by distances of 0.4 cm.

Figure 2 is a plot of resistance against temperature for the dye-graphite complex between 77 and 333 K. Between 77 and 250 K, the resistance is seen to be proportional to the temperature, with a slope of 0.1 ΩK^{-1} . At temperatures above the softening point (40 C-60° C), the curve again becomes linear, with a slope of 22 ΩK^{-1} . Furthermore, four-probe resistivity measurements have shown the resistivity to have the same dependence on temperature as the resistance. Unlike most organic complexes based on Little's model¹¹, this complex is rather unique in that over the temperature ranges investigated, there seems to be no activation energy. Furthermore, between 77 K and 250 K the proportional relationship between resistance and temperature is not unlike that for metals at temperatures greater than the Debye temperature. It should be stressed that this complex does not necessarily form a stoichiometric ratio. Resistance measurements indicate that the graphite is gradually converted from a semiconducting state to a 'metallic' state by

Fig. 1 Molecular structure of malachite green dye showing the two resonance structures which correspond to a positive formal charge on the two amine groups.

Fig. 2 Plot of resistance against temperature for malachite green dye-graphite complex.

increasing dye concentrations. Further increased dye concentrations convert the graphite back to the semiconducting state.

If the conductive properties of this complex result from an e-e interaction, the fact that it does not exhibit a 'high' temperature superconducting state, if a superconducting state at all, is an extremely complicated problem. Malachite green has an absorption band in the region 600–700 nm. Calculations¹² show that it is necessary to have more polarisable dyes, with absorption bands in the region of $\sim 1,200$ nm, to induce a sufficient e-e interaction in the spine. Furthermore, it is expected that the e-e interaction depends strongly on the distance separating the dye and the spine. For large separations, the interaction decreases rapidly¹² whereas for short separations (strong interaction) exchange interactions can occur between the conduction electrons in the spine and the dye molecule. Such exchange interactions could limit the strength of the e-e interaction in the spine, by the conversion of the dye to a 'stable', less polarisable radical. Nevertheless, if further measurements confirm the 'metallic' state of this complex, or class of complexes, it would indicate that the Coulomb interaction between localised electrons in the conjugated graphite sheet is greatly reduced. Such screening of the Coulomb interaction by the dye would then allow electron delocalisation to the extent that a 'metallic' state results.

We believe that this complex is only one of a rather large class of similar compounds based on the intercalation of triphenylmethane dyes (general class) and 'layer type' semiconductors and conductors. Examples of such 'layer type' semiconductors include graphite, MoS₂, and BN; whereas, TaS₂ and WS₂ are examples of 'metallic' layer compounds. Results of further detailed investigations concerning these compounds in the polycrystalline and single-crystal state will be published elsewhere.

We thank H. Williams, F. Parham, and M. Caspar for helpful discussions.

Rotation of the geomagnetic field

THE geomagnetic field apparently drifts westward about the geographic axis at about $0.2^\circ \text{ yr}^{-1}$. Malin & Saunders have attempted to determine the directions of the axes about which a 'westward' drift would best fit the fields during six successive epochs¹. They did not determine the circular standard deviations of the axis directions but, as the five successive axes moved fairly smoothly through an arc of about 20° , they assumed that the axes had been reasonably well determined, and interpreted the movement in terms of physical processes in the Earth's core.

The axes they determined were, however, almost certainly not those appropriate to their interpretation, and it is unlikely that the correct axes can be determined to a useful accuracy.

They made a numerical search for that combination of axis and drift which maximised the correlation between a function f , specified on the surface of a sphere at one epoch, and the corresponding function F five years later; that is, they looked for that combination which maximised the mean value of f^*F over the sphere, where f^* is the rotated version of f . This process is in fact exactly the same as searching for that combination of axis and drift which minimises the mean square of the difference $(F - f^*)$, a problem in least squares. This, in turn, is exactly the same as fitting the difference $\Delta F \equiv (F - f)$ by the difference $\delta f \equiv (f^* - f)$ by least squares, that is, fitting the integrated secular variation by the 'westward' drift of the field.

The functions f and F were specified in terms of a finite series of coefficients, g_n^m , h_n^m and G_n^m , H_n^m , for $n = 2$ to 6, of (semi-normalised) spherical harmonics defined with respect to the geographic axis. Correspondingly ΔF can be specified in terms of coefficients ΔG_n^m , ΔH_n^m , and, after some manipulation, δf in terms of δg_n^m , δh_n^m . Because the spherical harmonics are orthogonal over the sphere, minimising the mean of $(\Delta F - \delta f)^2$, is the same as minimising the sum

$$S = \sum_n \alpha_n \sum_{m=0}^n [(\Delta G_n^m - \delta g_n^m)^2 + (\Delta H_n^m - \delta h_n^m)^2], \quad (1)$$

where α_n is the mean square value over the sphere of the function produced by a unit amplitude harmonic n , m ; because of the normalisation, α_n is independent of m .

The axis of drift may be obtained from the geographical axis by a rotation having components $(u, v, 0)$ in the $\lambda = 0^\circ$, $\lambda = 90^\circ$, and $\theta = 0^\circ$ axes respectively, and the westward drift rate about the new axis may be denoted w . For convenience the westward drift $[(u, v, 0); w\delta t]$ may be denoted by Ω .

To perform the rotation of axes, Malin and Saunders used the Taylor series method of James². As u and v were at most 14° , and $w\delta t$ was about 1° , it is sufficient to take the series to second order for the following discussion. This shows that, for example,

$$\delta g_n^m = w \delta t (m h_n^m + b u^2 + c u v + d v^2), \quad (2)$$

where b , c , and d are linear combinations of the coefficients g_n^m , h_n^m , with $m' = m - 2, m - 1, m, m + 1, m + 2$, but with all the terms having the same value of n . Thus while the secular variation produced by the drift is proportional to w , the first order terms in u and v have cancelled. This confirms the intuitive result that the effect of a small 'westward' drift is going to be very insensitive to a small change of drift axis. It follows that the values found for u and v will be much more uncertain than those for w . Intuitively, if w is uncertain by, say, 10%, then we would expect u and v to be uncertain by about 0.1 rad, about 6° .

For a given epoch, the problem of estimating the best values of the parameters u , v , w by least squares can now be considered, that is, the minimisation of the sum S of (1). This corresponds to fitting a 'dependent' variable by a function of an 'independent' variable, the function having known form but involving the parameters which are to be determined. The coefficients of the integrated secular variation, ΔG_n^m , ΔH_n^m , are the values of the 'dependent' variable and, although specified, they are subject to considerable error. They are to be fitted by δg_n^m , δh_n^m , which are complicated functions of the values g_n^m , h_n^m of the 'independent' variable (which in comparison are effectively exact), and of the parameters u , v , w , which are to be estimated. The resulting estimates of these parameters will be subject to errors, which will increase as the errors in ΔG_n^m , ΔH_n^m become larger. As the rotation of axes does not introduce any terms of different n , the separation of S into contributions of different n is still possible. If these contributions were separately minimised five different values of Ω would be obtained, which can be called Ω_n . (Richmond³ showed that, for drift about the geographic axis, the w_n ranged between 0.01 and 0.23° yr⁻¹.) Malin⁴ estimated the standard deviations of ΔG_n^m , ΔH_n^m used by himself and Saunders¹. The fractional errors were about 10% for $n = 2$, increasing to about 50% for $n = 6$. Clearly the Ω_n would be subject to considerable errors, larger with increasing n . (For drift about the geographical axis it can be shown, using conventional error theory, that Malin's figures would give standard deviations of w_n varying from 0.01 to 0.04° yr⁻¹; the effect of introducing the other two parameters u and v is probably small, but will always increase these values.)

Because of the cancellation in (2) of the first order terms in u and v , the least squares problem is non-linear even to the first approximation, and it is not possible to perform an analysis of its solution. The α_n parameters in (1), however, clearly behave as 'weights' in the least squares solution; if one of the α_n parameters were considerably larger than the others then Ω may be expected to depend mainly on that Ω_n .

In the discussion of their results, Malin and Saunders interpreted Ω as the angular motion of the outer layers of the electrically conducting fluid core. The magnetic lines of force in the core are probably 'frozen' to the fluid on the short time scales of the secular variation, and the interpretation of Malin and Saunders would be reasonable if the functions they had correlated were the radial magnetic fields at the surface of the core. It appears, however, that what they did correlate were the magnetic potentials at the surface of the Earth. For a unit amplitude harmonic n , m , the mean square potential on the Earth's surface is $1/(2n + 1)$, whereas the mean square radial field is $(n + 1)^2/(2n + 1)$, and the extrapolation down to the core gives another factor of $(1.83)^{2n}$; the α_n used by Malin and Saunders over-weighted the $n = 2$ harmonics by about 700:1 compared with the $n = 6$ harmonics. This would not have mattered if the field rotated bodily without changing its pattern, but different harmonics do have different drift rates, and the drift contributes only about half of the secular variation. Rich-

mond³ has shown the large differences in w which result from using these different weightings. Therefore the Ω obtained by Malin and Saunders are almost certainly not those appropriate to their interpretation.

Because of the very high weighting of the harmonics of low degree, the fairly smooth variation of Ω is probably mainly an indication of the fairly smooth, and comparatively well determined, changes of the small number of $n = 2$ coefficients. Their weighting also means that Ω will have smaller errors than the correct Ω ; for drift about the geographic axis, and using the standard deviations of Malin⁴, their weighting gives a standard deviation of w of about 0.005° yr⁻¹, whereas the correct weights give about 0.022° yr⁻¹, corresponding to about 1½° and 7° respectively for the axis directions. So a recalculation of Ω using the correct weights would be expected to give a much bigger scatter of the drift axes, and make any movement of the axes much more difficult to determine.

But using coefficients up to only $n = 6$ to calculate Ω does not in any case give a reasonable approximation to the rotation of the core surface. The contribution of the secular variation coefficients of a given degree, n , to the mean square field at the core surface forms one term of a series which shows no sign of convergence up to $n = 6$, and the contribution of the higher coefficients is not known⁵.

DRS MALIN AND SAUNDERS REPLY: Lowes questions our conclusion on the grounds that the pole positions are not sufficiently well determined to show significant departures from the geographical pole.

In the absence of a satisfactory method for estimating the standard errors of the pole coordinates (Lowes gives an intuitive figure of about 6° , whereas our intuition, based on consistency of results, would give a smaller figure), we will attempt to test the validity of our results by the traditional method of a 'crucial experiment'. If our results are valid, they would predict that the optimum pole positions for epochs before 1940 would lie near the magnetic pole-Novaya Zemlya line and that their distance from the geographical pole would increase with the remoteness of the epoch. Further, we would expect the rotation rate to be smaller for earlier epochs. Alternatively, if the pole of rotation is really the geographical pole, we would expect the earlier optimum pole positions to be randomly distributed about the geographical pole.

We selected a uniform set of spherical harmonic models for the epochs 1905, 1915, 1925, 1935, 1945, derived from the main field and secular change models of Vestine *et al.*¹ and listed by Barraclough². The models are to the sixth degree and order, and are based on grid-point values of North and East magnetic intensity read from charted values of survey, repeat station, and observatory data. Although these data are less uniformly distributed with time than those used in our previous study, they are the best available at present. The method of determining the optimum pole positions and rotation rates is the same as that which we used previously³, and the results are given in Table 1. The results for 1925-1935 are in parenthesis because the rotation

TABLE 1 Pole positions and rotation rates required to give maximum correlation between magnetic field models for different epochs

1935-45	1940	10	58.6	23.6	-0.098

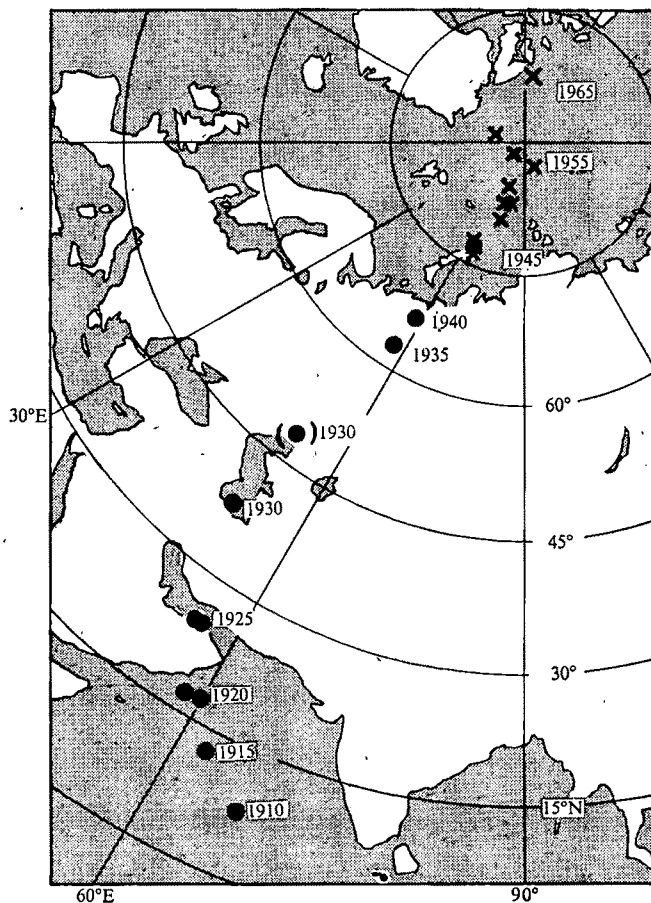

FIG. 1 Position of the optimum pole of rotation of the non-dipole part of the geomagnetic field.

between these epochs is very small and therefore the pole position is poorly determined (for a zero rotation the pole position would be indeterminate). In fact, the 1925-1935 correlation coefficient shows several maxima, and the position quoted represents only a local maximum.

The pole positions are plotted as circles on a zenithal equidistant chart (Fig. 1), together with the pole positions (indicated by crosses) obtained previously³. The results are in excellent accord with the prediction based on our earlier results. The second prediction, that the rotation rate should be smaller for earlier epochs, is also confirmed, though rather more spectacularly than we might have expected, because the rotation rate apparently drops to zero near 1930, and for earlier epochs shows the opposite sign. This is illustrated in Fig. 2, again circles and crosses denote present and previous results respectively.

Thus, the present results amply confirm our conclusion that, in general, the optimum pole of rotation of the non-dipole part of the geomagnetic field differs significantly from the geographical pole.

We have also suggested a physical interpretation of the phenomenon, based explicitly on the assumption that the rotation of the field reflected similar movements of the outer layers of the core. There are two separate parts to this assumption: (i) that the field rotates as a whole; (ii) that this rotation corresponds to a similar rotation of the outer core. It is the first of these parts that has been challenged by Lowes.

FIG. 2 Rate of rotation of the non-dipole part of the geomagnetic field about the optimum pole.

Lowes uses 'field' to denote the magnetic intensity, whereas, following Chapman and Bartels⁴, we allow it a more general meaning. Also, for 'rotation of the field', we should have written 'rotation of inhomogeneities of the field' (F. J. Müller, private communication), since rotation of an axi-symmetric field about its axis of symmetry would produce no secular change and therefore would not be detected in our investigation. For convenience, however, we retain the shorter notation.

If the whole of the secular change could be fitted by a simple rotation of the main field there would be no problem, since all the features of the field (potential, components of intensity, and so on) would yield the same pole position and rate of rotation for whatever height or depth they were analysed. It is clear, however, that such a simple model cannot account for all the complex changes in the field pattern. In the presence of such non-rotational components the derived pole position and rate of rotation will depend on the relative weights given to the individual spherical harmonic coefficients. [Two extreme examples are the potential at the surface, considered here, where the weighting is $(2n + 1)^{-1/2}$ (to convert from Schmidt semi-normalisation to full normalisation), and the vertical intensity at the core-

mantle interface, favoured by Lowes, where the weighting factor is $1.83^{n+2} \cdot (n+1) \cdot (2n+1)^{-1/2}$.]

Lowes asserts that the most appropriate rotation to investigate in connection with motions of the outer layers of the core is that of the vertical intensity at the core/mantle interface, but goes on to show that, because of the high weight given to the poorly determined high-degree coefficients relative to the better determined low-degree coefficients, the resulting pole positions would be of low significance. He further suggests that secular change coefficients of degree greater than six, which are too small to be determined significantly at the surface, might well contribute a major proportion of the secular change at the core/mantle interface. For these reasons, we prefer to consider the rotation of the field at the surface, where the observations are made, and where the secular change can be well represented by spherical harmonic coefficients to the sixth degree and order. Assuming, as before, that the non-dipole field is 'frozen in' to the core, the argument may be stated as follows: if the core rotates about the deduced pole position at the deduced rate then it will reproduce the observed secular change as accurately as is possible with a simple rotation.

We concede that such a simple model is inadequate to account for all of the observed changes in the non-dipole field, but it represents a better approximation (even when the additional degrees of freedom are taken into account) than westward drift. Moreover, it has the merit of making predictions about the diurnal variation of latitude which may be tested by astronomical observation³. There seems little point in pursuing a more sophisticated physical model until the quality and distribution of secular change data permits a more reliable determination of high degree spherical harmonic coefficients.

Electron diffraction on liquid water

X-RAY diffraction has been successfully used in determining radial distribution function in liquid water (see references in ref. 1). The few attempts²⁻⁷ to apply diffraction of a high energy electron beam to the same end in liquids in general has not led to usable diffraction patterns, particularly in the case of liquids of higher vapour pressure⁷. To overcome the difficulties arising from the strong absorption of electrons, we produced in an electron microscope a very thin layer of liquid water nearly in equilibrium with its vapour and prevented the pressure in the vicinity of the electron beam for increasing by evaporation. The liquid layer scattered the penetrating electron beam and usable diffraction patterns could be obtained.

A chamber⁸ for an electronoptical device Zeiss EF-4 was constructed for producing a water film of controlled thickness

and temperature. The film was created by wiping a drop of the liquid over a hole 2 mm in diameter in a copper plate of thickness 0.02. This was enclosed in a chamber connected to the vacuum space only by two apertures, one of diameter 70 μm for the entering primary beam and the other of diameter 200 μm for the scattered beam. Drop and film could be reproduced many times by a suitable mechanism.

In order to avoid quick disappearance of the water film, the vapour escaping through the apertures could be replaced by evaporating the water stored in the chamber.

Usually, the primary electron beam was completely absorbed immediately after the water film was produced. By slow evaporation the thickness of the film decreased and a pattern of diffuse Debye-Scherrer rings could be seen. This was photographed on a 9×12 cm Agfa-Gevaert Scientia 23D50 plate at distances of 20, 42 and 80 cm from the water film. Thus, the ranges of the scattering angle θ and the usual parameter $s = (4\pi/\lambda) \sin(\theta/2)$ could be varied. In order to avoid a predominance of scattering at very small angles, we used an s^2 rotating sector 2 mm over the photoplate. The intensity distribution $I(s)$ on the photoplate was determined by a Zeiss GIII Schnellfotometer. The exposure time was 1 to 3 s depending on the sample-to-plate distance. Short exposure times are of particular importance in scattering from solutions in which concentration changes during the experiment are to be avoided.

Figure 1 shows a diffraction photograph (a negative print) on water at 4° C. It was taken at a sample-to-photoplate distance of 42 cm using a monochromatic electron beam of energy ~ 67 keV, corresponding to a wavelength of 0.045 Å determined experimentally. The radial distribution function in the liquid was calculated by Fourier transformation of that part of the scattered intensity which could be assumed to be coherent scattering. This was determined arbitrarily in the

Fig. 1 Diffraction photograph (negative print) of water at 4° C.

Fig. 2 Radial distribution function for liquid water, H_2O , at 4°C . a, Electron diffraction; b, X-ray diffraction^{1,9}.

following way. The modified experimental molecular intensities

$$sM(s) = s[I(s) - I_B(s)]/I_B(s)$$

were obtained by arbitrarily drawing in smooth background curves $I_B(s)$ on the total experimental molecular intensity $I(s)$ curves. The Fourier transformation

$$f(r) = \int_{s_{\min}}^{s_{\max}} sM(s) \sin(sr) ds$$

of the $sM(s)$ function was carried out in the s range 1.7 to 9.5 \AA^{-1} using $\Delta s = 0.10 \text{ \AA}^{-1}$ steps.

The obtained radial distribution curve (Fig. 2a), which is not much altered by variations in the background curve, shows almost exactly the same maxima as the corresponding curves obtained from X-ray diffraction (Fig. 2b)^{1,9}.

According to the interpretation of other authors, these peaks must be ascribed, in the order of increasing r , to interactions O—H (intermolecular), O...O interactions between immediate neighbour molecules and second and more distant neighbours.

In the interaction between radiation and matter, the main difference in principle between X rays and the electron beam is that the former are diffracted by the electron clouds whereas the latter is scattered by the electric potential, depending on the steric configuration of the nuclei and the density distribution of the electrons. Consequently, electron diffraction allows the determination of the position of light atoms in the presence of heavy atoms. Therefore, in the case of water, more reliable information about the hydrogen-bonds can be expected.

The energy of the electron beam generally used in diffraction experiments corresponds to a wavelength λ of some hundredths of an Angström. This is at least ten times less than the wavelength of the X rays used for structural studies. Thus, the s range used in Fourier transformation for obtaining radial distribution from coherent intensity is much greater for electrons and so the cutoff error is reduced by comparison with X rays.

The ratio of the intensity of coherently scattered radiation to that of incident radiation is a few orders of magnitude higher in the case of electrons than in the case of X rays.

This leads to the practical conclusion that although an exposure time of a few seconds is sufficient for electrons, several hours are necessary for X rays.

BIOLOGICAL SCIENCES

Method for relating the structure and properties of chemical compounds

THE structure diagrams of chemical compounds are widely used in the communication of chemistry. They are also used in chemical information systems, mainly as keys for the retrieval of associated information¹. However some chemical information systems hold property data as well as structure diagrams in machine-readable forms²⁻⁵. If structure-property relationships could be investigated easily within chemical information systems, then the usefulness of the systems would be considerably increased. Described below are some results which have been obtained during investigation of structure-property relationships using a combination of regression analysis and some techniques of chemical structure handling used in information systems.

The method used is empirical⁶⁻⁸. The structures were coded manually as redundant connection tables and put in to the computer with the properties of the compounds. The rest of the processing was carried out automatically. A structural fragment was generated on each atom in each structure. Each fragment consisted of the central atom, the bonds it forms and the atoms to which it is bonded (excluding hydrogen atoms). Fragments of this type have been investigated⁹⁻¹⁰ and used as screens (M. F. Lynch *et al.*, personal communication, and ref. 11) in substructure search systems and for the automatic classification of chemical structures¹².

It was assumed that the value of the property under investigation, y , of the i th compound is related to its structure by the equation

$$y_i = \sum_{j=1}^n b_j x_{ij}$$

where there are n types of structural fragment in the set of structures and x_{ij} is the number of times that the j th fragment occurs in the i th structure. The constants b_j were determined by carrying out a regression analysis using a computer manufacturer's statistical analysis programs¹³.

The method was tested with a group of 79 penicillins and using the percentage serum binding as the property parameter¹⁴. They were chosen because they form a large group of structures for which property data have been published.

These compounds have also been studied using a semi-empirical structure-property correlation method and the results are available for comparison¹⁴.

An automatic analysis of the 79 penicillins in terms of the structural fragments described above showed that they contain 52 different fragment types. Eight of these however were derived from the penicillin nucleus and always occurred the same number of times in a structure. They were therefore omitted from the analysis. Also one group of four fragments and three groups of two fragments had within group correlation coefficients of 1 and thus only one fragment from each group was included. The regression analysis also excluded variables which were not significant at the 10% level.

The results of the regression analysis¹³ are shown in Table 1. The multiple correlation coefficient is 0.993 with 66 degrees of freedom ($F = 390$, $F_{12, 60, 0.001} = 3.32$) and the residual error 9.73. A regression carried out using log (amount of penicillin bound to serum/amount free) as the independent variable¹⁴ gave a multiple correlation coefficient of 0.945 with 70 degrees of freedom and a residual error of 0.294. It will be seen in Table 1 that all of the fragments except HO-C have regression coefficients which are different from zero at a significance level of 5%. The fragments which have negative regression coefficients and thus reduce serum binding are hydrophilic whereas the fragments with positive regression coefficients, which increase serum binding, are hydrophobic. The relationship between the hydrophobic nature of the side chain and serum binding of penicillins has been noted by other authors^{14, 15}.

This method differs from others published in that both the side chain and nucleus are treated in the same manner and both are broken down into fragments automatically¹⁶. It would be possible to integrate this kind of analysis easily into a computerised chemical information system. As structural fragments are developed from structure diagrams, the procedure will not resolve some isomers. This situation may be improved by using larger structural fragments, or more pre-

cise forms of structural representation than the connection table used in this work. The method is subject to the usual restrictions connected with the use of multiple regression analysis. We hope to publish a more detailed account of this and related work in the near future.

Results of the regression analysis using the serum binding percentage as the dependent variable and the occurrence of structural fragments as independent variables. The perfectly correlated fragments have correlation coefficients of +1 with the fragments in the left hand column and were not included in the calculation. All bonds are in chains except those denoted by asterisks which are delocalised ring bonds.

Terminal riboadenylate transferase in human lymphocytes

TERMINAL riboadenylate transferase (TrT) catalyses the transfer of adenylate residues from ATP to the 3'-hydroxyl group of certain polyribonucleotides in the presence of Mn²⁺. Enzymes of this kind may be involved in the processing of heterogeneous nuclear RNA to mRNA in eukaryotic cells, since many types of mRNA have terminal poly(A) sequences. Evidence for this is rather fragmentary and is complicated by reports of several forms of poly(A)-polymerising activities in both nucleus and cytoplasm¹⁻¹⁰. Clearer evidence might be obtained from systems that could be experimentally manipulated to show variation in the levels of activity of poly(A) polymerases and rates of mRNA synthesis. We have found that human lymphocytes exhibit increased TrT activity as part of their response to stimulation by phytohaemagglutinin (PHA) *in vitro*. This is the first mammalian, non-viral system in which increases in TrT activity have been observed with changes in the physiological state of the cell. The PHA-stimulated lymphocyte may be suitable for combined polymerase-mRNA turnover studies designed to clarify enzymatic steps in mRNA processing and terminal poly(A)

TABLE 1 Stimulation of polymerase activities in lymphocytes cultured with phytohaemagglutinin

Lymphocytes	Terminal riboadenylate transferase		Nucleus		Maxipolymerase		Minipolymerase	
	Bulk	Gradient	Bulk	Gradient	Cytoplasm Bulk	Nucleus Bulk		
Unstimulated (48 h)	28	24	0	0	1.3		0.14	
	33	15	0	0	1.2			
	21	21	0	0	1.3		0.14	
PHA-stimulated (48 h)	81	80	13	0	7.8		0.76	
	84	94	9	0	8.1		0.24	
	—	127	0	0	5.6		0.54	
	69	60	—	—	5.7		0.23	
	119	—	6	6	7.7		0.40	

Lymphocytes were cultured in RPMI-1640 tissue culture medium (Gibco) supplemented with 20% foetal calf serum, penicillin and streptomycin. Stimulated cultures (a) contained 0.2 ml Difco PHA-P stock PHA per 250 ml and controls (b) received no PHA. After the appropriate time, lymphocytes were suspended to a cell density of 1×10^6 cells ml^{-1} in TKM-sucrose buffer containing 50 mM Tris-HCl pH 7.6, 25 mM KCl, 5 mM MgCl_2 , and 0.25 M sucrose. The cells were counted, homogenised and fractionated by differential centrifugation¹⁷. The crude fractions were assayed for several enzymes directly and after velocity sedimentation through a 5–20% sucrose density gradient¹⁷. Assays for maxi and mini DNA-dependent DNA polymerases were as previously described¹⁷. The bulk assays have a total volume of 250 μl and the gradient assays were in 60 μl . The assays for TrT activity contained 0.2 M Tris-HCl, pH 8.25, 0.01 M rA(pA)₁₈, 0.5 mM ^3H -rATP (3.9 c.p.m. pmol^{-1}), 0.5 mM MnCl_2 , 4mM 2-mercaptoethanol, 0.1 mg ml^{-1} bovine serum albumin and enzyme. Reaction mixtures were incubated at 35° C. For the bulk assay aliquots were removed from the reaction mixture at various times, spotted on GF/C filters, and processed for acid-insoluble activity¹⁷. Enzyme-specific activity is expressed as nmol nucleotide incorporated per 10^6 cells h^{-1} . Each line in the table represents a separate experiment.

addition, since Rosenfeld *et al.*¹¹ have reported increases in poly(A)-rich mRNA during lymphocyte transformation by PHA.

For our studies, normal human lymphocytes were separated on Hypaque-Ficoll gradients¹² and incubated with PHA (Table 1). Stimulation was monitored morphologically and there was routinely 60% blast transformation after 48 h. Thymidine pulses indicated maximal DNA synthesis at 72 h and the number of cells had approximately doubled by 96 h. For enzyme analysis cultured lymphocytes were collected by centrifugation, washed in TKM sucrose, disrupted by homogenisation, and separated into nuclear and soluble cytoplasmic fractions by differential centrifugation. In some experiments, nuclear and cytoplasmic extracts were layered on sucrose density gradients for velocity gradient fractionation. TrT and several DNA polymerase activities were assayed (Table 1.) The oligonucleotide normally used to assay TrT, rA(pA)₁₈, was prepared by controlled hydrolysis of poly(A)₁₃.

Increases in polymerase activities following treatment of lymphocytes with PHA are shown in Table 1. A typical velocity gradient separation of polymerase activities from 48 h stimulated lymphocytes is presented in Fig. 1. Direct assay of nuclear and cytoplasmic extracts (bulk assays) and

summation of gradient activities showed that most of the total TrT activity was recovered from the gradient in a single peak with an estimated molecular weight of 60,000. The stimulation of the cytoplasmic high molecular weight or 'maxi' DNA polymerase confirms the work of other investigators and will not be discussed further^{14,15}. The activity of the low molecular weight or 'mini' DNA polymerase found in the nucleus may also increase, but its activity was always much lower than that of the cytoplasmic DNA polymerase (Table 1).

The time courses of TrT, maxipolymerase and thymidine incorporation during PHA stimulation are illustrated in Fig. 2. In general TrT activity increases three to six-fold, reaching a maximum after about 48 h. Since the cytoplasmic TrT

FIG. 1 Velocity gradient fractionation of polymerase activities. The soluble, cytoplasmic supernatant fractions (0.25 ml) prepared as described¹⁷ were layered on 5–20% sucrose density gradients in 50 mM Tris-HCl pH 7.6, 100 mM KCl, 1 mM 2-mercaptoethanol and 0.1 mg ml^{-1} bovine serum albumin. The gradients were centrifuged for 16 h at 40,000 r.p.m. (100,000g) and then collected in 20 fractions. Enzymes were assayed as described in Table 1. a, Stimulated lymphocytes; b, normal lymphocytes.

FIG. 2 Variation of polymerase activities with time after addition of PHA to cultures of human lymphocytes. For thymidine pulses, 1×10^6 cells were incubated for 2 h with 5 μCi ^3H -thymidine at 37° C. The cells were then pelleted and precipitated with cold 5% trichloroacetic acid (TCA). The TCA precipitate was collected on GF/C disks, washed, dried and counted in a liquid scintillation counter. Thymidine incorporation was linear during this time. Enzyme assays are described in Table 1. ●, Cytoplasmic TrT; ○, cytoplasmic 'maxi'; ▲, ^3H -thymidine incorporation; △, nuclear 'mini'.

assay was linear with both time and concentration of extract when a long oligoadenylate initiator was used, we feel this result is unambiguous. Cytoplasmic DNA polymerase activity and thymidine incorporation peaked at 72 h just before cell division. Most cells underwent mitosis between 72 and 96 h with a doubling in cell number. Synchronisation of cell division is good in this system. Increase in TrT activity in lymphocytes was prevented by cycloheximide addition at any time during lymphocyte activation by PHA.

The TrT activity which we detected was a soluble enzyme in the cytoplasmic fraction, was Mn^{2+} -dependent, required an oligonucleotide initiator and had a molecular weight of approximately 60,000. In crude extracts we found that an initiator 12–16 nucleotides long was optimal for detecting this activity. A low level of activity was found in the nucleus, but this result is difficult to interpret, since the enzyme could have leaked from the nucleus or bound adventitiously to chromatin upon cell breakage.

Table 2 illustrates the effects of several chemical compounds on TrT activity. Rifampicin-SV, α -amanitin and actinomycin D are all inhibitors of mammalian DNA-dependent RNA polymerases. These drugs have no effect

TABLE 2 Effect of chemicals on terminal riboadenylate transferase activity

Compound added	Percent inhibition
α -Amanitin	
8.5×10^{-6} M	1.2
1.4×10^{-6} M	0
Rifampicin	
96 μ g ml ⁻¹	0
160 μ g ml ⁻¹	0
Proflavin sulfate	
10 μ g ml ⁻¹	17
100 μ g ml ⁻¹	98
Actinomycin D	
20 μ g ml ⁻¹	3
50 μ g ml ⁻¹	2
N-Ethylmaleimide (NEM)	
0.8 mM	82
4 mM	99

TrT assays were carried out as described in Table 1. All compounds except NEM were added to the reaction mixtures. For experiments using NEM, the supernatant fraction was incubated in ice for 10 min with NEM before the addition of reaction mixture.

on TrT activity at concentrations which would inhibit RNA polymerase. Proflavin sulphate at a concentration of 100 μ g ml⁻¹ inhibits TrT. This compound also inhibits the purified TrT from calf thymus (F.J.B. unpublished data) and a similar activity in vaccinia cores¹⁶. Human TrT is a sulphhydryl enzyme, since it is completely inhibited by 4 mM N-ethylmaleimide (NEM).

These findings indicate that TrT is an enzyme distinct from DNA-dependent RNA polymerases. Its activity increases three to six-fold during PHA stimulation of the human lymphocyte. The role it plays in RNA processing and the addition of poly(A) sequences to the 3'-terminus of mRNAs may be studied more rigorously in this system which exhibits biological variation.

Is terminal deoxynucleotidyl transferase a somatic mutagen in lymphocytes?

AN enzyme able to add deoxyribonucleotides to the ends of DNA primers has been identified in calf thymus by Bollum and his colleagues and named terminal deoxynucleotidyl transferase^{1–4}. Chang⁵ has indicated that the enzyme is a specialised constituent of thymus cells and is not present in any other organ of several animal species. The enzyme is located in the lymphocyte fraction of the thymus (Silverstone, Parkman, McCaffrey and Baltimore, unpublished results). Recently, we found an enzyme with the properties of a terminal transferase in circulating lymphoblasts of patients with acute lymphoblastic leukaemia (ref. 6 and McCaffrey, Harrison, and Baltimore, unpublished results).

It seemed to me possible that terminal transferase could act as a mutagen, diversifying those molecules of the T lymphocyte which carry the immunological specificity of the cell. Although I realise that the question of which molecules give specificity to thymus-derived lymphocytes is open^{7,8}, I have assumed that the molecules are probably similar, if not identical, to antibody molecules. The hypothesis I wish to discuss is therefore that terminal transferase acts as a somatic mutagen to diversify the amino acid sequence in the variable region of immunoglobulin molecules. There are various hypotheses as to how the variety of amino acid sequences arises in the V regions of immunoglobulins⁹. I have assumed that somatic mutation plays a significant role: if all antibody synthesis is directly specified by inherited V regions^{9,10}, my proposal is clearly meaningless.

Numerous models of immunoglobulin diversification^{11–17}, which originate in the writing of Lederberg¹⁸ and Burnet¹⁹ postulate that most V regions arise by a process of somatic mutation onto which is superimposed a selective pressure. Starting from these models, I wish to suggest, as did Brenner and Milstein²¹, that the mutations arise because single-stranded gaps are made in an inherited gene which encodes the V regions of an immunoglobulin, and that during the repair of these gaps, an enzyme inserts the wrong base (or wrong bases), causing a mutation. Terminal transferase

Fig. 1 Schematic representation of hypothetical mutagenic activity of terminal transferase in concert with other enzymes.

would be the mutator and thus would be the somatic 'generator of diversity'¹².

The biochemistry of terminal transferase is consistent with this model. The enzyme will add mononucleotides sequentially to any 3'-OH-terminated segment of DNA and will add the nucleotides independent of any template direction³. Ordinarily, free single strands are used as primers but the enzyme can act at gaps in double-stranded molecules almost as effectively as it does on single-stranded primers (ref. 20 and Panet, McCaffrey, Smoler and Baltimore, unpublished results).

Because terminal transferase acts non-specifically at 3'-OH ends, it must be directed to the appropriate V region in order to act on that gene but not on others. One possibility is that immune lymphocyte precursors contain a site-specific endonuclease which produces, possibly in concert with an exonuclease, the gaps at which terminal transferase can act.

A specific form of this model is presented schematically in Fig. 1. I postulate that an endonuclease makes several single-strand scissions in the V region gene of an immunoglobulin chain. Three sites of endonuclease cleavage in the V region gene are suggested because of the data from Wu and Kabat²¹ showing three hot spots of variability in the V region (hypervariable regions). The nicks are then elongated to variable length gaps by an exonuclease. The repair of one gap is shown in detail (Fig. 1). Initially, terminal transferase inserts a single, random nucleotide which, in this case, does not form a base pair with the nucleotide on the opposite strand and is therefore a mutated site. The gap is then filled by an ordinary DNA polymerase and sealed by a ligase. The filling of a gap containing a mismatched base pair at the 3'-OH end can be catalysed by a mammalian DNA polymerase²².

I postulate that a process such as that depicted in Fig. 1 causes mutations at the hypervariable positions in the V region genes^{21,23}. There are extensive differences in amino

acid sequence between V regions which are located outside the hypervariable regions. Such variation is probably due to multiple, inherited genes and not to somatic mutation²⁴⁻²⁶. These inherited differences include differences between species, differences between the subclasses of variable regions within the antibodies of a given species and differences due to allelic genetic polymorphisms in a single gene. It is significant that when data on one class of antibodies in a single inbred strain—the lambda chains of Balb/c mice—were collected^{27,28}, all the amino acid substitutions were in the hypervariable regions. In kappa chains of Balb/c mice, however, extensive variation occurs throughout the V region, suggesting the existence of many inherited V region genes²⁴. Even in the kappa chains, however, when proteins were analysed which were virtually identical outside the hypervariable regions, variability localised to the hypervariable regions was evident²⁶.

All this speculation relates to the production of circulating antibodies, but terminal transferase is found in thymocytes and it is not clear whether such cells have antibody on their surface. Some class of molecules resembling antibody must be involved in T cell specificity, however, and whatever those molecules, it seems reasonable that some of their variability arises in a manner similar to that of antibody variability.

To try to relate this model to antibody synthesis by B lymphocytes and plasma cells, we have sought terminal transferase in cells from the chicken's bursa of Fabricius. In agreement with previous results⁵, no terminal transferase like that in the thymus was evident in bursal cells (McCaffrey, Smoler and Baltimore, unpublished results). A high concentration of a unique replicative DNA polymerase which might make mistakes is, however, found in bursal cells (McCaffrey, Smoler and Baltimore, unpublished results). Immunoglobulin synthesis in B cells might therefore also involve a process of somatic diversification analogous to that described here for thymus cells. There could, however, be significant differences between the mechanisms of T and B cell diversification.

The molecular model suggested here is much more detailed than is justified by existing data. It is presented merely to show the context in which terminal transferase might act as a mutagen to diversify immunoglobulin structure. The only elements I wish to stress are the potential ability of the enzyme or enzymes like it to produce somatic variability in an inherited gene and the occurrence of such an enzyme in thymic lymphocytes. Terminal transferase could, for example, be involved in the type of somatic diversification discussed by Cunningham²⁹.

I thank Dr R. McCaffrey for criticism of these ideas and Dr M. Weigert for stimulating this line of thinking. This work was supported by a contract (Virus Cancer Program), and a grant from the National Cancer Institute.

Complementation of a defect in the production of ribosomal RNA in somatic cell hybrids

THE use of cell hybridisation for complementation tests is hampered because the establishment of a hybrid cell line may involve rearrangement of both parental cells' genetic material, and often loss of chromosomes¹⁻³. Since it is difficult to recognise single chromosomes, the genotype of the hybrid cannot be determined easily. Furthermore, strong selective pressures are often applied to isolate hybrid cells. Thus, the appearance of the wild type phenotype in a hybrid between a mutant and a wild type cell does not always imply that the mutation is recessive and can be complemented by the wild type allele: alternative hypotheses must be considered.

We isolated⁴ a temperature sensitive (*ts*) mutant from the Syrian hamster cell line BHK21/13, *ts422E*, which cannot grow at 39° C because at this temperature a block after formation of the 32S precursor prevents the production of 28S rRNA and 60S ribosomal subunits in the cytoplasm, while 18S rRNA and 40S ribosomal subunits are produced normally. The mutation seems to be in a gene coding for a protein involved in the processing of rRNA, the most likely possibilities being a ribosomal protein or an enzyme⁴.

The mutation seems to be recessive as it can be complemented in intraspecific hybrids with many other *ts*BHK mutants. These hybrids can all grow at 39° C⁵. In principle, the *ts422E* defect could be complemented in a hybrid cell by two different mechanisms. (a) The processing defect of *ts422E* could be relieved by the gene product of the wild type allele so that 28S rRNA transcribed from both parental cell genomes would be produced at 39° C. (b) The wild type phenotype could also be produced if synthesis of rRNA in the hybrid cells were sustained exclusively by the *ts** parental genome, while production of rRNA transcribed from the *422E* genome would still be inhibited. The latter mechanism would imply that the *ts422E* mutation is not recessive, but rather partially dominant, or else it is a mutation which cannot be complemented in *trans*. We have therefore investigated how the *ts422E* mutation is complemented in hybrid cells. We took advantage of the differences in the electrophoretic mobility of the 28S rRNAs of different species^{6,7}. Since it has been shown that in mouse-hamster hybrids, the 28S rRNA of both species is synthesised⁸, we isolated hybrids between *ts422E* and mouse cells, and determined the type of 28S rRNA formed at 33° C and 39° C.

Cell culture conditions were as described before^{4,5}. *ts422E* cells were hybridised with two lines of mouse cells, C2F, a thymidine kinase deficient derivative of 3T3 cells⁹, and TG8, a hypoxanthine, guanine phosphoribosyl transferase (HGPRT) deficient derivative of 3T6 cells¹⁰. Cells were fused in the presence of β -propiolactone inactivated Sendai virus, and incubated at 33° C for 2 d. Hybrids were selected at 39° C in HAT (aminopterin 10⁻⁵ M, thymidine 4 \times 10⁻⁵ M, hypoxanthine 10⁻⁴ M) medium¹¹. *ts422E* cannot grow at 39° C and the mouse parental cells are killed by the HAT medium. Hybrid colonies appeared with a frequency of about 10⁻⁴. Colonies were isolated and propagated at 39° C in HAT medium for two passages before transfer to 37° C in non-selective medium. Their chromosomal constitution was determined as described¹². 28S rRNA was analysed in six hybrid clones, four from the C2F cross and two from the TG8 cross, selected on the basis of their chromosome complement, that varied from a majority of hamster chromosomes

* This hybrid had a bimodal chromosomes distribution, with about one-third of the mitotic figures having a modal number of 85 telocentric and 43 bi-armed.

† In arbitrary units, 1 corresponds to the ratio radioactivity in 28S rRNA/radioactivity in 18S rRNA obtained in wild type cells labelled with ³H-uridine for 2 h at 39° C or 3 h at 33° C, as described in Fig. 1.

‡ Calculated as described in Fig. 1.

Fig. 1 Polyacrylamide gel electrophoresis of 28S rRNA from hybrid C7. Cells were shifted to 39° C or 33° C and after 2 d pulsed with ^3H -uridine ($4 \mu\text{Ci}$, $0.04 \mu\text{g ml}^{-1}$) for 2 h at 39° C and 3 h at 33° C. Cells were then washed twice with cold, isotonic Tris-buffered saline (pH 7.4) and the cytoplasmic fraction was prepared as previously described⁴. RNA was purified by two phenol extractions at room temperature and precipitated with two volumes of 95% ethanol, at -20° C. RNA was layered on linear 15-30% sucrose gradients (34 ml) in SDS buffer (0.1 M NaCl-0.5% SDS-0.01 M Tris-HCl, pH 7.2) and centrifuged at 24,000 r.p.m. for 16 h at 23° C in a SW 27 Spinco rotor. For each sucrose gradient, 1 ml fractions were collected from the bottom of the tube and the radioactivity of an aliquot was counted. The 28S rRNA peak was pooled and ethanol precipitated. 28S rRNA was fractionated by polyacrylamide gel electrophoresis: gels contained 2.6% (w/v) acrylamide and 0.13% (w/v) N, N'-methylene bisacrylamide, and were polymerised in a buffer containing 20 mM Na acetate, 1.0 mM NaEDTA, 40 mM Tris-acetate, pH 7.2, 0.2% SDS, 10% glycerol. Electrophoresis was run at room temperature, at 5 mA per gel, for 48 h in a buffer containing Tris, pH 7.2, Na acetate, NaEDTA and SDS in the same concentrations as in the gel. The desired portion of the gel was sliced frozen into 1 mm slices, solubilised in 0.5 ml of an NCS-water mixture (9:1) at 60° C overnight, and counted in a toluene-based scintillation fluid. Each 28S rRNA sample was run together with a ^{14}C -labelled marker of 28S rRNA prepared from 3T3 mouse cells or BHK cells. A, 28S rRNA (^3H) from hybrid C7 growing at 33° C (●), hamster 28S ^{14}C rRNA (○); B, 28S rRNA (^3H) from hybrid C7 growing at 39° C (●), mouse 28S ^{14}C -rRNA (○); C, 28S rRNA (^3H) from hybrid C7 growing at 39° C (●), hamster 28S ^{14}C rRNA (○); D, 28S rRNA (^3H) from hybrid C7 growing at 39° C (●), mouse 28S ^{14}C rRNA (○). Electrophoresis is from left to right. The percentage of mouse and hamster 28S rRNA produced by the hybrid was estimated by calculating the areas under each curve, which were assumed to be symmetrical.

to a majority of mouse chromosomes. Since the mouse parental lines are free of bi-armed chromosomes, the chromosome contribution of each species to the hybrids can be determined by assuming that the ratio of bi-armed to telocentric of the parental hamster cells remains unchanged (Table 2).

For the preparation of 28S rRNA, cells were labelled with ^3H -uridine for 2 h at 39° C and 3 h at 33° C (Fig. 1), to ensure that the appearance of 28S rRNA in the hybrids at

39° C would not be due to the small amount of 28S rRNA produced in *ts422E* cells at this temperature; this is generally not detectable with pulses of up to 2 h⁴. A normal amount of 28S rRNA was produced in all hybrids at both temperatures.

On polyacrylamide gels hamster 28S rRNA moves ahead of mouse 28S rRNA⁸. The 28S rRNA from each gradient was analysed on 2.6% polyacrylamide gels, 35 cm long, run for 48 h, together with appropriate markers. The separation obtainable in these conditions is shown in Fig. 1.

A summary of the results obtained with all hybrid clones examined is shown in Table 1. Hamster 28S rRNA was synthesised in all hybrids at both temperatures. The amount of hamster 28S rRNA in the hybrids varies from 20% to 90% of the total 28S rRNA, but in each hybrid was the same at 33° C and 39° C. Thus, the mutation of *ts422E* cells can be complemented by the wild type allele provided by the mouse genome.

To show that this was not due to extensive chromosomal rearrangements or selection of hybrid lines with specific chromosome losses, we fused TG8 and 422E cells in the presence of Sendai virus. After 2 d of cocultivation at 33° C, the cells were plated in HAT medium at the same temperature. After 3 d, they were shifted to 39° C and kept one more day in HAT medium. After a further 24 h, they were labelled for 2 h with ^3H -uridine, and the 28S rRNA produced was analysed on polyacrylamide gels. This killed most of the mouse cells, which could not grow in HAT medium, while *ts422E* and hybrid cells were unaffected. In this population, production of 28S rRNA can be ascribed chiefly to surviving mouse cells, or mouse-*ts422E* hybrids. Accordingly, the results showed that total production of 28S rRNA was very low and, most important, 16% of this RNA was of hamster origin. In cells treated similarly in the absence of Sendai virus, hamster RNA constituted less than 4% of the total 28S rRNA. Thus, the defect in ribosome production of *ts422E* can be relieved before extensive chromosomal rearrangements in the hybrid cell, as it can be demonstrated as early as 5 d after hybridisation, corresponding to probably less than three generation times.

These findings also prove that the *ts* mutation leading to defective processing of *ts422E* rRNA does not reside in the rRNA itself, for if it did, this RNA would not be susceptible to proper processing even in hybrid cells. It is also interesting that, with respect to the protein(s) involved in rRNA processing, there can be an exchange of products between cells of different species, as mouse gene-product(s) seem able to function in the processing of hamster rRNA.

It has been reported that in mouse-hamster hybrids, when the chromosomes of one species constituted most of the chromosomes of the hybrid, a disproportionately higher percentage of rRNA of that species was present⁸. We do not find this relationship in all our hybrids (Table 2), and at least two (T2 and C16) produce approximately equal amounts of mouse and hamster 28S rRNA. It does not seem likely that this discrepancy is due to different methods of labelling the cells (2-3 h compared with steady state label in ref. 8)

TABLE 2 Chromosomal constitution and production of hamster and mouse rRNA of *ts422E* × mouse cell hybrids

Hybrids	Modal chromosome No.			Total hamster*	% Hamster chromosomes	% Hamster 28S rRNA
	Telocentric	Bi-armed	Total mouse*			
C7	38	56	22	72	76	71
C12	70	58	53	75	58	85

C16	70	58	55	35	39	49

Production of hamster 28S rRNA was calculated as described in Fig. 1 and Table 1.

* Estimated by assuming that the number of hamster telocentrics is proportional to the number of bi-armed chromosomes.

for labelling our hybrid cells for 2 or 24 h did not substantially change the proportion of mouse and hamster 28S rRNA. This discrepancy is more likely to reside in the nature of the hybrid lines examined: we examined ours soon after formation, but Eliceiri⁸ examined hybrids which had undergone extensive propagation and recloning¹². If the production of predominantly one species of 28S rRNA conferred even a slight growth advantage to these cells, this would lead to the selection of stable hybrid lines containing predominantly rRNA of one of the two species.

Changes in a surface-labelled galactoprotein and in glycolipid concentrations in cells transformed by a temperature-sensitive polyoma virus mutant

In hamster cells transformed by a temperature-sensitive mutant of polyoma virus we have found that the external label in a galactoprotein disappears and the cellular concentration of lactosylceramide increases when the cells are grown at the permissive temperature. These changes can be reversed at the non-permissive temperature.

Three kinds of major membrane changes involving glycoproteins and glycolipids are associated with malignant transformation. They are (1) enhanced agglutinability of cells by some sugar-binding proteins (lectins)¹⁻³; (2) blocked synthesis of gangliosides⁴⁻¹⁰, neutral glycolipids¹¹⁻¹³, fucolipids^{14,15} and some glycoproteins¹⁶ with occasional accumulation of precursor glycans^{4,6,10}; and, (3) enhanced synthesis of sialofucoglycopeptide^{17,18}. Recently a method for surface-labelling cells using galactose oxidase followed by treatment with tritiated sodium borohydride has been used to distinguish between surface galactoproteins of normal and transformed cells¹⁹. A galactoprotein which was labelled in normal hamster NIL cells was not labelled in polyoma-transformed NIL cells, and the introduction of label into this surface moiety seemed to be a correlative of growth control.

The enhanced agglutinability of transformed cells¹⁻³ has been linked directly to the control of cellular multiplication

in two types of transformed cells harbouring thermosensitive mutations. In one case, what is believed to be a mutation in a cellular gene results in the restoration of regulated growth and decreased agglutinability at the restrictive temperature, while the cells seem to be transformed at the permissive temperature^{20,21}. The same phenomenon is observed in cells transformed by thermosensitive polyoma virus mutant ts3^{22,23}.

We have initiated an investigation of the biochemical basis for the thermosensitive changes in the surface membrane of polyoma ts3-transformed BHK cells. Since topoinhibition of DNA synthesis is also rendered thermosensitive in these same cells²², we speculate that the temperature-dependent surface alterations that we have observed may be implicated in the control of DNA synthesis.

BHK cells transformed with temperature-sensitive polyoma virus (BHKpyts3 Cl 7C), those transformed with wild type polyoma virus (BHKpywt Cl 4), and their progenitor cells (BHK Cl 13) were obtained from Dr W. Eckhart at the Salk Institute. Each cell line was grown in Dulbecco's

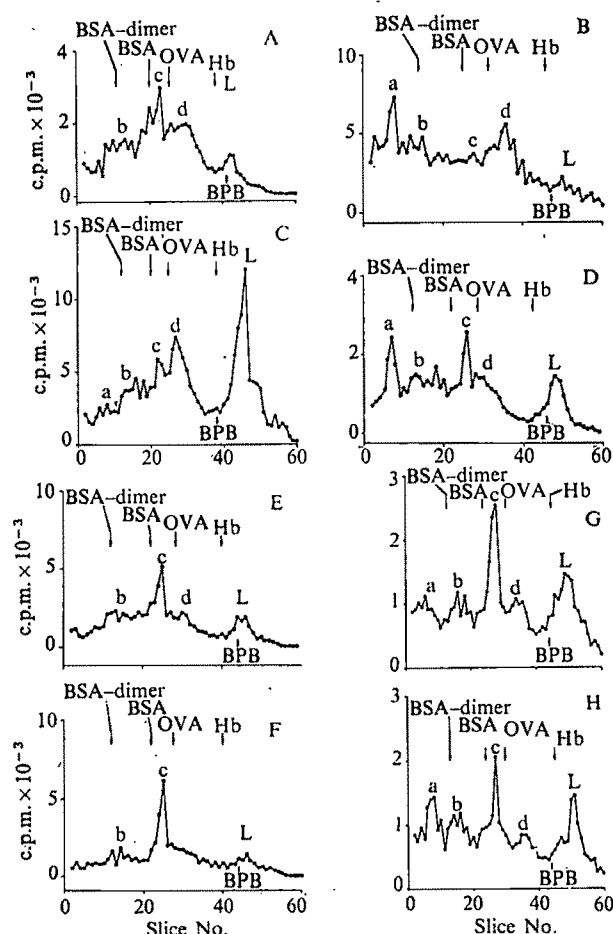

Fig. 1 Profile of external galactosyl label in baby hamster kidney fibroblasts (BHK C13) on acrylamide gel electrophoresis in sodium dodecyl sulphate. Cells were treated on the plates with 10 Worthington units of galactose oxidase for 1 h at room temperature, taken off with EDTA, and labelled as described previously¹⁹. Graphs show subconfluent non-transformed BHK at 32°C (A) and growing at 39°C (C); confluent non-transformed BHK at 32°C (B) and at 39°C (D); wild-type-polyoma-transformed BHK at confluency at 32°C (E) and at 39°C (F) ts3-transformed BHK at confluency at 32°C (G) and at 39°C (H) Acrylamide concentration was 5%; slicing, counting and preparation of internal ¹⁴C-labelled standard proteins were as previously described¹⁹. BSA, bovine serum albumin; OVA, ovalbumin; Hb, haemoglobin; BPB, bromo-phenol blue. Note that galactoprotein a is only pronounced in confluent, non-transformed cells and in BHKpyts3 at non-permissive temperature. Peaks c and d are non-specifically labelled by sodium borotritiate alone. L = lipid label.

TABLE 1 Dependence of galactoprotein a label on cell density in normal BHK cells, cells transformed with wild-type polyoma virus (BHKpywt) and with *ts3*

Cells	Temperature (°C)	Presence or absence of galactoprotein a label		
		Sparse*	Subconfluent†	Confluent‡
BHK normal	32	—	—	++
	39	—	+	++
BHKpywt	32	n.d.	—	—
	39	n.d.	—	—
BHKpyts	32	n.d.	—	—
	39	n.d.	+	++

The apparent molecular weight of galactoprotein a was approximately 200,000. —, Absent; +, obviously present; ++, present in high quantities; n.d., not determined.

† Cells touching but not saturated.

‡ Cells at saturation density.

modified minimum essential medium containing 10% foetal calf serum at the permissive (32° C) and non-permissive (39° C) temperatures for the *ts3* gene function.

Surface labelling was achieved on cells growing on plastic dishes by the method described previously¹⁹. Glycolipids were extracted with chloroform-methanol and isolated by acetylation: the glycolipids were separated on thin-layer chromatography into fractions lactosylceramide, trihexosylceramide and haematoside. Each fraction was extracted from silica gel with chloroform-methanol-water (1:1:0.1) and the extracts were methanolysed, and the sugars liberated were determined as trimethylsilyl derivatives with myo-inositol as an internal standard by gas-liquid chromatography.

As Table 1 and Fig. 1 show, in cells grown to their maximum saturation density by changing the medium frequently, a surface galactoprotein of BHK with a molecular weight of 200,000 (galactoprotein a) was not labelled in BHKpywt either at 32° C or at 39° C, nor was it labelled in BHKpyts3 at 32° C. However, galactoprotein a of BHKpyts3 was labelled when the cells were grown at 39° C; where they acquired normal morphological appearance, decreased agglutinability with lectins and increased topoinhibition of DNA synthesis.

In actively growing, sparse or subconfluent BHK cells, galactoprotein a was not labelled, whereas it was labelled when growth was inhibited at the saturation density.

As Table 2 shows, in BHKpywt the chemical concentration of lactosylceramide was obviously higher than that of normal BHK cells, and the concentration of trihexosylceramide was considerably reduced. The concentration of lactosylceramide was also sharply increased in BHKpyts3 at 32° C but not at 39° C, whereas the concentration of haematoside was depressed. It is noteworthy, however, that the concentration of trihexosylceramide was quite low at both temperatures in BHKpyts3.

Recently, Hammarström and Bjursell²⁴ observed that isotope incorporation from ¹⁴C-palmitate into trihexosylceramide depends on cell population density and decreased

considerably when the cells were transformed with wild type polyoma virus, in agreement with our previous findings¹⁰. Also consistent with their results, the decreased synthesis of trihexosylceramide in BHKpyts3 at the permissive temperature was not restored at the non-permissive temperature, indicating that decreased synthesis of trihexosylceramide is not essential for expression of certain aspects of the transformed phenotype. Similarly, the growth behaviour in agar and the serum requirement of BHKpyts3 are not known to be temperature-sensitive²², although topoinhibition of DNA synthesis and agglutinability by lectins are temperature-sensitive^{22,23}. Thus, although trihexosylceramide reduction accompanies transformation by polyoma virus, it is not under the control of the *ts3* gene function and therefore does not seem to be implicated in the regulation of cell growth.

A considerable increase of lactosylceramide in some clonal isolates of BHKpywt had also been observed previously⁴. Our results suggest that increased lactosylceramide could be essential for expression of crucial aspects of the transformed phenotype, including the regulation of growth.

The inability to label galactoprotein a in the transformed state shows a good parallel with the appearance of lectin agglutinability, as demonstrated reversibly in BHKpyts3 at permissive and non-permissive temperatures²³. The labelling of the galactoprotein in non-transformed cells at confluency is consistent with an increased reaction of galactosyl residues with *Ricinus communis* protein as observed by Nicolson²⁵. Our surface labelling procedure did not label lactosylceramide of either transformed or non-transformed BHK cells, in agreement with the finding that the lactosyl moiety may not protrude towards the outside of the cells or that the length of the lactosyl moiety is too short to be externally labelled due to steric hindrance.

Perfect reversibility in the labelling of galactoprotein a and the lactosylceramide and haematoside concentrations in BHKpyts3 between permissive and non-permissive temperatures suggest that these membrane parameters are related

TABLE 2 Glycolipid concentration of BHK cells, those transformed with wild-type and with *ts3*

	Temperature (°C)	Glycolipid Concentration $\mu\text{mol per 100 mg dry weight}^*$

to growth control in BHK cells. It is possible that deletion of galactoprotein a initiates uncontrolled DNA synthesis, as the loss of this protein has been observed after trypsin treatment of BHK and NIL cells (our unpublished observation), and since trypsin is known to induce the initiation of S-phase, and mitosis²⁶.

Enhancement of radiation lethality of *E. coli* B/r by procaine hydrochloride

MANY carbonyl compounds by virtue of the electron affinitive property¹ of their C=O groups are good radiosensitisers in bacterial as well as mammalian cells²⁻⁴. The electronic charge distribution at the carbonyl bond of some local anaesthetics belonging to the class of esters represented by the general formula (I) given below is also known to play an important

role in their anaesthetic action⁵⁻⁸. If these esters are found to be radiosensitisers they may prove very valuable in radiation therapy. Here we present data on one such compound, procaine hydrochloride (II) which is commonly used as a local anaesthetic and has been found to enhance radiation lethality of *Escherichia coli* B/r under anoxia.

E. coli B/r cells grown to stationary phase in nutrient broth (Difco) were suspended in 0.1 M phosphate buffer (pH 7) at a concentration of approximately 2×10^8 cells ml⁻¹. The cell suspension was irradiated in a ⁶⁰Co γ-ray source at a dose rate of 8 krad min⁻¹ and the radiation dose was measured by ferrous sulphate dosimetry. The cell suspension was deoxygenated by bubbling oxygen-free nitrogen before and during irradiation. Sodium nitrate (Analar) and commercially available medical grade nitrous oxide were used as electron scavengers. Procaine hydrochloride (USP) obtained from Hoechst Pharmaceuticals (India) was used without further purification. Toxicity of procaine hydrochloride towards bacteria was determined up to a contact time of 100 min in buffer and only non-toxic concentrations were used in the present studies. Irradiated samples were diluted in sterile phosphate buffer, inoculated into Petri plates and overlaid with nutrient agar (Difco) previously melted and held at 48° C. A minimum of 500 colonies of bacteria were counted at the end of 18 h incubation at 37° C. All the survival curves represent data from experiments repeated at least three times with replicate plates at all dilutions. From the exponential part of the survival curves plotted on a semi log scale, *D*₁ (dose for 1% survival) values were obtained and the dose modification factor (DMF) was calculated as the ratio of *D*₁ in the presence of procaine HCl and that of the control cells.

Procaine HCl at a concentration of 250 μM enhanced the lethality of *E. coli* B/r cells on irradiation under anoxia (DMF = 0.54). It can be seen from Table 1 that a further increase in procaine concentration did not show proportionate decrease in DMF. Whereas procaine HCl was effective also when cells were irradiated under anoxia in nutrient broth, there was no effect if cells treated with the chemical were thoroughly washed before irradiation. Procaine HCl irradiated in aqueous solution under anoxia did not show any toxic effects on unirradiated bacteria indicating that the enhancement of the radiation lethality was not due to some stable toxic products of the anaesthetic. On the other hand, when irradiated cells were immediately mixed (within 1 min of irradiation) with unirradiated procaine HCl there was a significant enhancement in the lethality (Table 1) implicating the inhibition of post-irradiation repair. This would also rule out the involvement of any short-lived transients of the chemical in this process. The fact that the effect of procaine HCl was observed even when irradiation was carried out in the presence of broth or in the presence of an efficient electron scavenger, NaNO₂, at equimolar concentrations (Table 1) further supports this view.

Whereas the actual mechanism still remains uncertain, procaine HCl was not found to react with cysteine (our unpublished results) as studied by Ellman's reaction modified by Butterworth *et al.*⁷ This could explain the result that cells treated with procaine HCl but irradiated after being thoroughly washed were not affected. The local anaesthetics and procaine HCl in particular, are known to interact with cellular membranes⁸ leading to various changes in membrane characteristics^{9,10}. Since membrane is believed to play an important role in the modification of radiation response of cells^{11,12} it is likely that the enhancement of radiation lethality by procaine HCl may be somehow related to its interaction with the bacterial membrane. The enhancement of damage by N₂O (ref. 13) (Table 1) could also be attributed to its anaesthetic action although alternative mechanisms¹⁴ have been suggested. Shortlived transients do not seem to play any significant role and so the observation that N₂O₂, which is also an electron scavenger, considerably reduced the effect of procaine HCl (DMF = 0.90) indicates a competition between the two anaesthetics for sites to interact with the cellular membrane, rather than with the radiolytic transients of water.

The ineffectiveness of procaine HCl under oxic conditions of irradiation still needs a satisfactory explanation. The following facts, however, must be kept in mind while suggesting any mechanism for this effect: (i) free radical intermediates may not be playing any role in enhancement of damage by procaine HCl; (ii) oxygen itself enhances radiation effects implicating the cellular membrane¹⁵; (iii) the radiation damage caused in presence of oxygen is generally non-repairable¹⁶.

Demonstration in mouse of X-ray induced deletions for a known enzyme structural locus

THE known lethal alleles at the albino locus of mice are radiation-induced and cause prenatal or early neonatal death. Four alleles expressed in the homozygous newborn as absence of pigment and early neonatal death (c^{1408} , c^{112K} , c^{65K} , and c^{2H}) were found to cause hypoglycaemia and deficiency of glucose-6-phosphatase and other enzymes¹⁻³. Two additional radiation-induced alleles (c^{6H} and c^{25H}) act as early embryonic lethals. Complementation tests between these lethal-albino alleles suggested that all six mutations could be deficiencies for genetic material other than just the albino locus⁴. Since X rays are known to produce small deletions^{4,5}, all six of these mutations have been tested with various closely linked genes using the standard deletion mapping procedure. Unfortunately, the two most closely linked genes to c , $taupe$ (tp) and shaker-1 ($sh-1$) (order with centi-Morgans (cM) distance, $tp - 2 - c - 4 - sh-1$), seemed not to have been deleted in any of the six lethal-albino mutations^{2,6}. Recently,

TABLE 1 MOD-2 phenotypes of individuals produced by crossing c^{ch}/c^* to SM/J mice.

Genotype of original c^{ch}/c^* individual	^a Untyped F ₁ offspring		^b Typed F ₁ offspring			
	MOD-2AB	MOD-2A	$c^{ch}/+$ MOD-2AB	MOD-2A	$c^*/+$ MOD-2AB	MOD-2A
$c^{14COS} Mod-2^?$ $c^{ch} Mod-2^b$	11	0	2	0	2	0
$c^{6H} Mod-2^?$ $c^{ch} Mod-2^b$	4	5	3	0	0	5
$c^{25H} Mod-2^?$ $c^{ch} Mod-2^b$	3	3	5	0	0	5

the gene mitochondrial malic enzyme (*Mod-2*) that codes for electrophoretic variants of mitochondrial malic enzyme (MOD-2: EC 1.1.1.40, L-malate: NADP oxidoreductase, decarboxylating) was shown to reside in chromosome 7 one cM from *c* between *c* and *sh-1* (ref. 7 and E. M. E. and D. L. Coleman, in preparation). We present evidence here showing that two of these mutations (c^{6H} and c^{25H}), but not the c^{14COS} mutation, are deletions that extend into the *Mod-2* locus.

Stocks of each of the lethal-albino alleles are maintained by brother-sister mating of heterozygous individuals containing the chinchilla (c^{ch}) allele at the *c* locus and one of the lethal-albino alleles (c^*). At the time of weaning, the phenotype of homozygous chinchilla (c^{ch}/c^{ch}) is darker than that of heterozygotes for chinchilla and albino (c^{ch}/c^*). In the crosses reported here, the normal *c* allele (+) was obtained from randomly-bred Swiss-Webster mice. The *Mod-2*^a allele was obtained from the SM/J strain maintained at the Jackson Laboratory. The lethal-albino stocks and the Swiss-Webster stock carried only the *Mod-2*^b allele.

Individual hearts were homogenised in one to two volumes of distilled water and then Triton X-100 was added to give approximately a 1% final concentration. The supernatant was prepared by centrifuging the homogenate at 20,000 *g* for 15 min and applied directly to the gel wells. Electrophoresis was performed in a Buchler Vertical Starch Gel Apparatus, cathode to anode, at 150 V for 18 to 20 h. The bridge buffer consisted of 0.233 M Tris base, 0.086 M citric acid (pH 7.0). The gel consisted of 12% Electrostar in a gel buffer of 0.0043 M Tris base, 0.0016 M citric acid (pH 7.0). The gel was sliced and stained according to the method of Shows *et al.*⁸

Individual c^{ch}/c^* mice (MOD-2B),¹ where c^* represents either the c^{6H} , c^{25H} , or c^{14COS} allele, were crossed to SM/J

mice (MOD-2A) and the *Mod-2* phenotype of individual offspring was determined (Table 1, Column a). In the cross involving c^{14COS} only one type of offspring was obtained, namely that with the heterozygous (*Mod-2*^a/*Mod-2*^b) phenotype, MOD-2AB. But in the crosses involving either c^{6H} or c^{25H} , segregation of two types of offspring occurred: those with the heterozygous (*Mod-2*^a/*Mod-2*^b) phenotype, MOD-2AB, and those that displayed the MOD-2A phenotype characteristic of the SM/J strain (Table 1). This raised the suspicion that perhaps individuals carrying one of the two lethal-albino alleles, c^{6H} or c^{25H} , might lack the *Mod-2* locus in *cis* position with c^* accounting for the lack of expression of the *Mod-2b* allele. This hypothesis was put to test by progeny testing these F₁ individuals derived from crosses of c^{ch}/c^* (MOD-2B) by $+/+$ (SM/J, MOD-2A). Crosses of these to a Swiss Webster albino stock (*c/c*), permitted the identification of the particular allele, c^{ch} or c^* , at the albino locus. Only those F₁s which carried c^{6H} or c^{25H} lacked the *Mod-2b* allele whereas this was present in all those F₁s carrying the c^{ch} -allele (Table 1, Column b and Fig. 1).

We believe this is the first demonstration in mammals of X-ray induced deletions for an identified enzyme structural locus. The c^{6H} and c^{25H} deletions extend in length at least 1 cM, since *Mod-2* is involved. Our data are also consistent with the genetic complementation map constructed for the six lethal-albino mutations where c^{6H} and c^{25H} complement with c^{14COS} but not with each other⁹. The data suggest that mitochondrial malic enzyme may be essential in embryonic development as the two lethal albino alleles in which its structural locus is deleted are early embryonic lethals.

Gene dosage in a deletion for a nuclear-coded, mitochondrial enzyme

It is a general principle of mammalian biochemical genetics that enzymatic activity is proportional to gene dosage; that is, co-dominance of the biochemical phenotype is usual in heterozygotes. A well studied exception is the lethal albino locus of mice. The radiation-induced lethal albino alleles cause prenatal or early neonatal death. The mutations are unusual in their lack of gene dosage effect. Four alleles (c^{1400} , c^{112K} , c^{65K} , c^{3H}) that are expressed in newborns as absence of pigment, hypoglycaemia, and neonatal death are associated with glucose 6-phosphatase deficiency^{1,2}. Heterozygotes distinguishable by pigment dilution have the same glucose 6-phosphatase levels as normal homozygotes in a number of situations, including enzyme induction with corticoids, glucagon, dibutyryl cyclic AMP, by producing alloxan diabetes, and during normal post-natal development^{3,4}. Four other enzymes (tyrosine aminotransferase, serine dehydratase, bilirubin glucuronyl transferase, and spectrophotometrically-determined cytochrome P-450) that are deficient in lethal albino homozygotes are present in normal levels in heterozygotes (refs 3-5 and M. M. Thaler, R. P. E., and S. Gluecksohn-Waelsch, in preparation). There is evidence that mutation of something other than structural genes for the enzymes is involved. Residual amounts of glucose 6-phosphatase and tyrosine aminotransferase are present in lethal albino homozygotes. Complementation of these lethal albino alleles with two additional lethal albino alleles, c^{6H} and c^{25H} obtained from Harwell, resulted in normal enzyme levels^{4,5}. Also, abnormalities of endoplasmic reticulum of lethal albino hepatocytes are strikingly evident on electron microscopy⁶. Enzymes deficient in homozygotes are either cyclic AMP-induced or microsomal. A mutation in the gene for a membrane structural protein or in the gene for a component of the cyclic AMP induction system has been suggested as an underlying defect which might account for the deficiency of a number of enzymes and the failure to demonstrate heterozygote dosage effect, although biochemical and immunological techniques have not yet detected any abnormality (R. P. E., P. Siekevitz, K. Jacobs, and S. Gluecksohn-Waelsch, in preparation).

It has been demonstrated that in two lethal albino alleles (c^{6H} and c^{25H}) which cause early embryonic death the deletion extends to the adjacent structural locus for mitochondrial malic enzyme (*Mod-2* EC 1.1.1.40, L-malate NADP oxidoreductase, decarboxylating)⁷. We compared malic enzyme activity in hearts and kidneys of lethal albino heterozygotes, which possess one copy of the structural gene, to their normal littermates, which possess two copies. A 2:1 ratio of enzyme activity is expected if dosage holds true. Typed offspring of the c^{6H}/c^{6H} or $c^{6H}/c^{25H} \times SM/J (+/+)$ had been tested by the cross to Swiss Webster (c/c)⁷. These

typed animals were either hemizygous (*Mod-2a*) or heterozygous (*Mod-2ab*) at the structural locus for mitochondrial malic enzyme.

Adult mice were killed by cervical dislocation. All operations were carried out at 0° C. 73% of malic enzyme in mouse hearts is mitochondrial⁸. Homogenates of individual hearts were prepared by homogenising minced tissue in 0.5 ml of distilled water. Triton was added to the homogenate to make a 1% solution, which was incubated for 15 min and then centrifuged at 700g for 30 min. The supernatant was collected for enzyme assay and protein quantification.

Kidney mitochondria were purified by homogenising the kidneys from individual animals in three volumes of 0.25 M sucrose in 0.01 M, pH 8 glycylglycine. The homogenate was centrifuged at 700g for 10 min. The supernatant was collected and spun at 8,700g for 15 min. The resulting pellet was resuspended in 1.0 ml of sucrose-glycylglycine and Triton was added to make a 1% solution. After incubating for 15 min, the preparation was centrifuged at 39,000g for 20 min and the supernatant saved for assay and protein quantification.

Assay for malic enzyme activity was carried out with a spectrophotometer measuring change in optical density at 340 nm at 37° C. The total volume was 0.2 ml and final concentrations of the reagents were: glycylglycine, 0.2 M; MnCl₂, 0.79 mM; NADP, 2 mM; and, L-malic acid, 16.5 mM. Malic acid was added to start the reaction after the other reagents and an appropriate dilution of enzyme preparation had equilibrated at 37° C for 5 min. Protein concentrations of the enzyme preparations were determined by Lowry's method which was not affected by the low concentrations of Triton X-100 present.

As seen in Table 1, about half as much malic enzyme was found in hearts from the hemizygous mice as was found in normal, heterozygous mice. The difference is highly significant. In fact, there is a better fit to the 2:1 ratio than is expected for material where only 73% of the enzyme is mitochondrial. Given the standard errors, the activity ratio is not greatly different than the expected 63.5:100. A significant difference was however not found with the purified kidney mitochondria although the trend is in the expected direction. The difference is not due to a different specific activity of the MOD-2A enzyme (the fast form solely present in the hemizygous mice) as *Mod-2a* homozygotes (SM/J strain) showed 35.0 ± 4.4 nmol per min per mg protein in hearts and 54.6 ± 5.6 nmol per min per mg protein in purified kidney mitochondria.

We conclude that the principle of gene dosage for enzymatic activity in heterozygotes also applies for a deletion in the structural gene of mitochondrial malic enzyme. This is in contrast to the failure to observe dosage effects in lethal albino heterozygotes with glucose 6-phosphatase and a number of other enzymes that are deficient in lethal albino homozygotes. It seems likely that these exceptions to gene dosage are related to a defect in a structural component, for example, microsomal membrane protein or in regulation rather than mutation of structural genes. Thus, gene dosage in mammals cannot always be explained by normal levels of enzymatic protein of which half is nonfunctional (but which might often be detected as CRM as has been found with human gal-1-P uridyl transferase deficiency⁹).

It is interesting that gene dosage is present for a nuclear coded mitochondrial enzyme. In yeast and *Neurospora*, blockage of mitochondrial transcription and translation stimulates synthesis of nuclear coded mitochondrial enzymes, suggesting that mitochondria make a repressor(s) regulating nuclear gene expression¹⁰. The finding that the deletion of one nuclear gene for a mitochondrial enzyme leads to a halving of the enzyme's activity would suggest that activator controls, if present in mammals, are not locus specific. The detection of human, nuclear controlled, mitochondrial en-

Amelioration of Marek's disease and absence of vaccine protection in immunologically deficient chickens

MAREK's disease (MD) is a lymphoproliferative disease of chickens which is generally considered to be neoplastic¹. It is probably the most commonly occurring neoplasm of any animal and until recently it caused extensive economic loss, estimated to be in excess of 150 million dollars annually, to the poultry industry². Several viral vaccines which will effectively prevent the disease have been developed³ and the most extensively used is a herpesvirus isolated from turkeys (HVT)⁴, which will prevent the disease in laboratory and field trials^{5,6}.

The characteristics of the protection are unusual. On vaccination, chickens develop persistent viraemia with HVT.

Also, vaccination with this virus does not prevent infection of the host with virulent MD virus (MDV), replication and persistence of the virulent virus in the host, and shedding of the virulent virus from the host^{6,7,8} albeit at a slightly lower level. Thus, the protection cannot be mediated entirely by immune mechanisms directed against virus replication and shedding. A variety of mechanisms have been proposed⁹⁻¹².

Cells constituting MD lymphomas could have originated from bursa, thymus or bone marrow¹. From antigenic marker studies, they are apparently predominantly thymus-derived lymphocytes^{12,13}. Also, neo-natal bursectomy does not interfere with MD induction¹⁴, and thymectomy decreased the proportion of genetically susceptible birds that died of MD or had MD lymphomas¹. The thymus cells of the tumour may have two roles: as a source of proliferative target cells or as a mediator of cellular immune response against the target cells. We show here that cyclophosphamide (CP) treatment significantly reduces the incidence of MD. Also, immunologically deficient chickens bursectomised with high doses of CP were not protected against MD by vaccination with HVT.

Chickens, highly susceptible to MD, were line 7 in experiment 1 or a cross between line 15 males and line 7 females in experiment 2 (ref. 15). The parent flocks are known to have antibody to MDV that is transmitted passively to the progeny. Progeny hatched and reared in isolation, however, are free of MDV and do not acquire antibody to MDV. All chicks were reared in modified Horsfall Bauer isolators. For virus isolation, approximately 2×10^7 spleen cells were inoculated on confluent DEF cultures prepared and maintained as described¹⁶. Plaques were counted 14 d after inoculation. Antibody to MDV was assayed by the agar gel precipitation test with antigen prepared in duck embryo fibroblasts¹⁷ or by the indirect fluorescent antibody test¹⁸.

To test for the ability of the chickens to produce antibody to sheep erythrocytes (SE), we inoculated groups of chickens at 4, 6 or 7, and 9 weeks of age with 1×10^8 to 2×10^8 erythrocytes at each of five sites per chicken. Serum was collected at the end of the experiments (8 weeks for experiment 1 and 11 weeks for experiments 2 and 3), and antibody was assayed by haemagglutination¹⁹. All birds dying during the experiment and all those that survived were examined for MD lesions by gross and histopathological methods²⁰. For chemical bursectomy, chicks were inoculated intramuscularly on the first 4 d of life with either 4 or 5 mg of CP d⁻¹ (Cytosan, Mead Johnson Laboratories, Evansville, Indiana). In previous experiments (H.G.P., unpublished), chicks of line 15 \times 7 inoculated with a total of 16 mg of CP were unable to produce antibody to SE, *Brucella abortus*, and bovine serum albumin, and most of the chicks were agammaglobulinaemic. The HVT strain FC126 in its eleventh duck embryo fibroblast passage⁴ was administered on day 6. The JM strain⁵ and cloned preparation of the GA strain²¹ of MDV, which were highly pathogenic, were used to induce

TABLE 1 Effect of cyclophosphamide on Marek's disease (Experiment 1).

CP	Treatment MDV	No. of Chickens	% Marek's disease response			Virus isolation	Antibody to:	
			Dead*	Gross†	Total‡		MD	SE

—	—	—	14	0	0		0

CP, Cyclophosphamide administered intramuscularly, 5 mg d⁻¹ for the first 4 d after hatching; HVT, the herpesvirus of turkeys inoculated intra-abdominally, 3,700 (PFU) per chick at 6 d of age; MDV, Marek's disease virus, GA strain, inoculated intra-abdominally, 33,000 (PFU) per chick at 6 d of age or 56,000 (PFU) per chick at 3 weeks of age. Experiment ended at 11 weeks of age.

*, †, ‡ See Table 1.

MD by inoculation on the sixth to seventh day of age or to challenge immunity by inoculation on day 21.

Treatment with 16 mg (Table 1) or 20 mg (Tables 2 and 3) of CP significantly reduced mortality ($P \leq 0.01$ when data from both times of exposure are pooled and compared in a one-tailed χ^2 test) and gross lesions ($P \leq 0.01$) of MD even when MD virus was given 3 weeks after CP treatment (Tables 2 and 3). When histological lesions were included, the differences were not significant. The CP-treated chickens tested were infected with MDV as the virus was isolated from most birds tested (Table 3) and most had MD lesions. None of those tested could respond with antibody to either viral antigens or SE. They were therefore deficient in bursa-dependent lymphoid functions.

Experiments 2 and 3 were designed to determine whether CP would affect protection by HVT. In both experiments, vaccinated birds not treated with CP, whose immunity was challenged with the GA (Table 2) or JM (Table 3) strains of MD at 3 weeks of age, were fully protected, those treated with CP had up to 90% MD, depending on the criteria used to measure the response. Thus, these chickens lacked the immunity to MD conferred on normal chickens by HVT. Virus re-isolated from both CP-treated and untreated chickens at the end of the experiment showed that they had become infected with HVT. Although some chickens died, most survived. These surviving chickens were unable to produce antibody to viral antigens. We conclude that they were deficient in their bursa-dependent lymphoid functions.

Among the two control groups not inoculated with MDV (Table 1) and one group inoculated with HVT (Table 3), 1, 2, and 2 birds, respectively, had mild lymphoid infiltrations in the nerves. This type of lesion has been described previously in isolated controls^{7,18,22} and is considered to be unrelated to MDV infection. The presence of viral plaques in cultures from two groups of birds that had not been inoculated with either MDV or HVT (Table 3) cannot be

explained because these groups of birds also lacked antibody to viral antigens.

Treatment with CP eliminated bursa-dependent immune functions and caused a temporary lymphoid depletion of the thymus²³. By 15 d, however, the appearance of the thymus had returned to normal, and at 1 month (the earliest time tested) it was functionally competent. Because surgical bursectomy and irradiation did not affect MD¹⁴ and because bursa-dependent lymphoid cells were only a small part of MD lymphomas^{12,13}, it was unlikely that the effect of CP on the bursa would have been responsible for the observed reduction in MD. Because thymectomy reduced MD lymphomas in susceptible chickens, the effect of CP on the thymus may possibly have accounted for the reduction in MD, particularly because a high dose of CP was used. Prolonged reduction of thymus-dependent function was not observed²³ however. Tests of thymus function during the development of MD in CP-treated chicks would be helpful in determining the role of the thymus. Also CP may possibly have affected bone marrow cells which may be involved in the pathogenesis of MD (ref. 1). A combination of these effects may also have occurred.

Protection against MD by HVT was largely absent in CP-treated chickens even though immunity was challenged when birds were 3 weeks old. The absence of protection was most likely due to the obliteration of bursa-dependent lymphoid cell function by CP although CP may also have had an effect on thymus function. The effect of CP on thymus function was not sufficient to prevent MD completely; some thymus target cell function or cellular immune response to target cells may have persisted. The role of the thymus-dependent immune system in immunity and the effect of CP on it are therefore still undetermined. If the bursa-dependent lymphoid system played a major role in protection induced by HVT vaccine, its effect was probably mediated through antibody to the tumour cell or virus-infected cell rather than through

TABLE 3 Effect of cyclophosphamide on Marek's disease and on protection offered by the herpesvirus of turkeys (Experiment 3).

CP	Treatment		No. of Chickens	Dead*	% Marek's disease response			Virus isolation	Antibody to:

CP, Cyclophosphamide administered intramuscularly, 5 mg d⁻¹ for the first 4 d after hatching; HVT, the herpesvirus of turkeys inoculated intra-abdominally, 4,000 PFU per chick at 6 d of age; MDV, Marek's disease virus, JM strain, inoculated intra-abdominally, 690 PFU per chick at 3 weeks of age; SE, sheep erythrocytes injected intramuscularly, 5×10^8 cells per chick at 4 and 6 weeks of age. Antibody to SE was measured by haemagglutination. Antibody to MDV was measured by the agar gel precipitation test. The experiment ended at 11 weeks of age.

*, †, ‡ See Table 1.

¶ Plaques in one of two replicates possibly due to procedural error.

antibody neutralising the virus. This is because cell-free virus accessible to neutralisation by antibody cannot be demonstrated in blood and internal tissues of MDV-infected chickens. The absence of an effect of vaccine-induced immunity on infection, replication, and shedding of the virulent virus from the host may also have resulted from the highly cell-associated nature of MDV within the body of the chicken. Nevertheless, we conclude that an immunosuppressive drug will eliminate HVT vaccine protection against MD.

We thank W. P. Kwolek, ARS, Peoria, Illinois, for statistical analyses.

Are non-dividing cells present in ageing cell cultures?

THE idea that an increased number of non-dividing cells accumulate during the growth decline of human embryonic fibroblasts (HEF) cultivated *in vitro* has been put forward¹. This concept of a non-dividing fraction of cells seems to be widely accepted^{2,3}, but no compelling evidence exists so far, to show that non-cycling cells exist in old cultures of human fibroblasts. On the contrary, it seems that most, if not all, the cells can divide up to the end of the lifespan of human

diploid cell lines. What seems to take place, however, is an increased transit time and heterogeneity of cell cycles^{4,5}.

The first experiments that analysed the kinetics of cell division of human fibroblasts at different passage levels^{4,5} showed a decrease in the number of cells which synthesised DNA during a 24 h labelling period and after a continuous labelling between subcultivation and confluency. This seemed to be caused by a prolongation of the generation time due to a delay in the G₁ and G₂ periods of the division cycle. It should be stressed that these experiments referred only to the time between a subcultivation and confluency and did not consider the possibility that cells which did not divide during one passage might do so in the following one. It was subsequently reported⁶ that the percentage of cells capable of division decreased with increasing age in tissue culture. The latter experiments, however, were done by plating 200 cells per 60 mm Petri dish so that each cell remained isolated, so it reveals the number of cells capable of dividing when cloned. This is completely different from how a cell behaves when in the proximity of other cells. It has also been shown⁷ that the percentage of cells capable of entering DNA synthesis after a 30 h labelling period at each passage of human diploid cell lines declines as a function of either time or population doublings. This technique also allows the evaluation of the age of the culture, which is much more precise than referring to the passage number.

These reports⁴⁻⁷ form the basis for the concept that non-cycling cells are present in increased amounts during cell senescence *in vitro*. The cells that did not synthesise DNA were not followed^{4,5,7} in subsequent passages however, and Merz and Ross⁶ analysed cell division in an environment unfavourable to the cell.

When phase II (20th passage) HEF were subcultivated with different split ratios, (cells from one flask were subcultivated by transfer into either another flask (1:1), into two flasks (1:2), or into 4 flasks (1:4)), and were labelled continuously, 21% of the cells synthesised DNA in the first group, 75% in the second, and 97% in the third group (Table 1). This shows that with higher inocula (1:1 and 1:2 splits) not all the cells have time to enter DNA synthesis before growth stops. After a 1:4 split however, almost all cells had time to enter the division cycle before they were affected by the mechanisms responsible for the inhibition of division during cell crowding. Thus, the results of an experiment with only a 1:2 split (which is the way these cells are usually carried) would have suggested that at this passage there are 25% non-dividers.

When HEF very near the end of their lifespan *in vitro* are labelled continuously with tritiated thymidine (³H-TdR) from the time of seeding to the time when further growth ceases, and are analysed by autoradiography, 66% of the nuclei become labelled during that time (Table 2). If identical cultures are subcultivated after that period and are again labelled continuously with ³H-TdR, 7 d after the second subcultivation 86% of the nuclei are labelled and 2 weeks later 92% of the cells are labelled. (The cultures were confluent from 17 d.) Thus only 8% of the cells remained unlabelled after the two last passages of this HEF line. This cannot be due to dilution of the non-dividers by dividing cells, for even if all the cells that had entered DNA synthesis

Cultures were labelled continuously by adding 0.01 $\mu\text{Ci ml}^{-1}$ specific activity 1.9 Ci mM^{-1} every 4d.

had divided, the non-dividing fraction would be diluted to 20%. Also, it was previously shown^{4,5} that in late passages the population does not double because many of the cells that enter DNA synthesis take a long time to reach mitosis, because they are delayed in the G_2 period.

With chick fibroblasts, nearly 100% of the cells divide between each subcultivation and confluency, in human fibroblasts however, a large proportion of the cells do not enter DNA synthesis during one passage, but do so during the following passage. This difference between human and chick cells could be explained on the basis of the increased heterogeneity of the cell cycles in human cells. As a result of this heterogeneity of generation times, when human cells reach saturation density some cells divide one or two times (short cycles) and others do not have time to complete their cycle⁹. In old populations, since this heterogeneity is more pronounced⁴, more cells are unable to complete the cycle before saturation density is reached. In chick fibroblasts, however, although the generation time also seems to be prolonged⁸, it is perhaps uniformly prolonged throughout the whole population, so that at each passage every cell has an equal chance of completing the division cycle before growth stops.

Whatever the reasons, in the systems studied so far, non-cycling cells do not seem to be a feature of cell ageing *in vitro*.

Androgen receptors in a Syrian hamster ductus deferens tumour cell line

We have established in culture a cloned line of hamster ductus deferens cells that contains a saturable, high affinity testosterone receptor protein. These cells exhibit an increased rate of DNA synthesis in response to testosterone and 5 α -dihydrotestosterone (DHT) treatment, although they probably do not require either androgen for survival. We believe

this is the first description of a cloned cell line that exhibits a growth response to a physiological dose of androgen. The mechanism of action of the steroid may be similar to that in the normal tissue of origin.

A transplantable leiomyosarcoma (Accession No. 14072, Experimental No. LX-7330-MU9-TB-MU1) from Syrian hamster ductus deferens tissue was obtained^{1,2} in March 1971. The original tumour from which the DDT₁ cells were established was induced in male hamsters by long-term administration of diethylstilboestrol (DES) and testosterone³. The tumour was autonomous when received but showed some T-binding activity (J. S. N., unpublished observation). The sarcoma was dispersed by trypsinisation and placed in culture in Ham's F-10 with 10% horse serum, 5% foetal calf

Fig. 1 a, Cells grown in roller culture were collected by shaking, pelleted at 800g, and washed 2 h in minimal essential medium (MEM) buffered with HEPES pH 7.6 at 4° C. Aliquots of cells in 10 ml of MEM were distributed evenly to 25 ml Erlenmeyer flasks and warmed to 37° C. 1, 2, 6, 7 ^3H -testosterone (Specific activity, 91 Ci mmol^{-1} New England Nuclear) dissolved in ethanol-MEM 1:1 was added at varying concentrations either alone or in combination with fifty-fold excess testosterone. At no time did the ethanol exceed 0.1%. Incubation was terminated at 75 min by withdrawing samples and immediately placing them on ice (all further operations are at 4° C unless indicated). All samples were centrifuged at 1,400g and washed twice with Tris saline pH 7.6. Bound ^3H -testosterone was extracted into 3 ml of absolute ethanol (at 21° C) and counted in 10 ml of a toluene based scintillation fluid (4 mg PPO + 50 mg POPOP per l toluene). Specific binding was calculated by subtracting non-specifically bound testosterone (^3H -testosterone + fifty-fold excess testosterone) from total bound testosterone (^3H -testosterone). Free ^3H -testosterone was measured directly from the incubation medium after centrifugation to remove the cells. Protein was determined by the method of Lowry⁵. Δ , Total; \diamond , specific; \circ , non-specific. b, Binding analysis was performed by the method of Scatchard⁹ and only specifically bound was plotted.

serum with 100 units ml^{-1} penicillin; 100 $\mu\text{g ml}^{-1}$ streptomycin, 2.5 $\mu\text{g ml}^{-1}$ fungizone (Gibco) and 1×10^{-9} M testosterone (Sigma). On reimplantation of the cells from culture into non-syngeneic Syrian hamsters, a new tumour developed and grew at essentially the same rate as the original. Since the tumour might consist of a heterogeneous cell population with a small number of cells responding to testosterone, a second trypsinisation was performed and the resulting cells were cloned in the presence of 1×10^{-9} M testosterone using Falcon microtest plates³. Cells from each clone were frozen in growth medium with 10% DMSO and saved for later analysis. Of the clones analysed to date, one designated DDT₁, has been shown to have a high steroid binding activity. The DDT₁ cell line shows several characteristics of a permanent cell line such as log-phase growth in suspension culture and formation of tumours on reimplantation into animals.

Several experiments have now shown that the DDT₁ cells respond to a physiological dose of testosterone or DHT by

FIG. 2 a, Sucrose gradient analysis was performed in linear 5–20% sucrose made up in 10% glycerol containing 20 mM Tris, 100 mM KCl, and 10^{-6} M phenyl methyl sulphonyl fluoride (PMSF) at pH 7.45. Gradients (4.8 ml) were prepared with a Buchler University Gradient Former and 0.2 ml fractions of 150,000g cytosol containing 2.3 mg protein were layered just before centrifugation at 45,000 r.p.m. for 17 h at 2° C in the Beckman SW 50.1 head. Five drop fractions were collected and counted at 25% efficiency in 13 ml of scintillation fluid (1 l of toluene + 4 gm PPO + 50 mg POPOP diluted to 1.3 l with absolute ethanol). Cytosol was prepared by homogenising the cells with 15 strokes of a dounce type B in 20 mM Tris, 2 mM MgCl_2 , 2 mM CaCl_2 , 0.5 mM mercaptoethanol, 1 μM PMSF, and 10% glycerol pH 7.45 (buffer A) at 2° C. The homogenate was centrifuged at 150,000g (Ave) in a Beckman type 65 head for 45 min at 2° C. 1, 2, 6, 7 ^3H -testosterone (Specific activity, 91 Ci mmol^{-1} , New England Nuclear) was added to buffer A to a concentration of 1.9×10^{-8} M and enough cytosol was added to dilute this to 1.9×10^{-9} M. Unlabelled steroids (testosterone or E_2) were added at a fifty-fold concentration (1×10^{-7} M) before addition of the cytosol. All the samples were incubated at least 2 h before centrifugation, (.....), ^3H -testosterone; (-----), ^3H -testosterone + testosterone; (—), ^3H -testosterone + E_2 . Sedimentation values were calculated by the method of Martin and Ames⁷ using bovine serum albumin (4.6S) and γ -globulin (7.0S) as standards. b, Whole cells were incubated for 1 h at 37° C in Dulbecco's Modified Eagle's medium (DME) with 25 mM HEPES buffer containing 6×10^{-9} M 1, 2, 6, 7 ^3H -testosterone (○—○) or 6×10^{-9} M 1, 2, 6, 7 ^3H -testosterone + 6×10^{-7} M testosterone (○—○). The cells were then washed twice in 3 ml Tris-saline pH 7.45 (all further operations at 2° C) in 12 ml conical centrifuge tubes and always centrifuged 5 min at 700g. The cells were washed a third time in buffer B (buffer A with 0.25 M sucrose instead of glycerol) and pelleted at 1,400g for 5 min. The cell pellet was transferred to a dounce type B and an equal volume of buffer B was added before homogenisation by 15 strokes. The resulting homogenate was centrifuged at 1,400g for 15 min. The nuclear pellet was resuspended by gentle vortexing and washed twice with 2 ml of buffer B. The nuclei were then diluted with an equal volume of buffer C (buffer A with 800 mM KCl) and extracted over 2 h with occasional gentle vortexing. The nuclear extract was centrifuged at 2,500g for 10 min and 0.2 ml of the supernatant containing 2.0 mg soluble protein was analysed on sucrose gradients (with the exceptions that the gradients contained 400 mM KCl) and then counted as described in (a).

increasing the rate of synthesis of DNA, as measured by incorporation of ^3H -methylthymidine (^3H -Tdr) into the hot perchloric acid soluble fraction of the cell (Table 1).

Since testosterone seems to stimulate the growth of the DDT₁ cells, we examined ^3H -testosterone retention in an intact cell system (Fig. 1). These studies indicate the presence of a high affinity receptor ($K_d = 8.5 \times 10^{-10}$ M) which is saturable at 3.6×10^{-14} M per mg protein. There are approximately 3,400 binding sites per cell.

Having demonstrated a high affinity, saturable retention of ^3H -testosterone with whole cells, we analysed this finding in a cell-free extract. Sucrose gradient analysis of 150,000g cytoplasm from the DDT₁ cells has repeatedly demonstrated a receptor binding ^3H -testosterone or its metabolites that sediments at 5.6–5.8s in 5–20% sucrose gradients made up in 10% glycerol as described in Fig. 2a. This binding is completely abolished when unlabelled testosterone is included in the incubation mixture. E_2 reduces the binding by 33.5%. Enzymatic degradation of the material in this fraction by trypsin (500 $\mu\text{g ml}^{-1}$) at 2° C for 2 h, but not RNase (500 $\mu\text{g ml}^{-1}$) or DNase (500 $\mu\text{g ml}^{-1}$), suggests that the receptor is a protein.

When whole cells are incubated 1 h in the presence of ^3H -testosterone, a receptor can be extracted from the nuclear pellet using a high salt buffer (Fig. 2b). The receptor sediments at approximately 5.1S and when unlabelled testosterone is added to the incubation media the 5.1S peak disappears.

The DDT₁ cell line seems to be the first cloned cell line that exhibits a growth response to testosterone and DHT

TABLE 1 Effect of DHT and testosterone on the rate of DNA synthesis in cell culture

* Values \pm s.d.

At the time the androgens were added there were 9.7 ± 0.4 μg DNA per plate.

Replicate cultures were plated at a density of 5.75×10^5 cells per 60 mm tissue culture dish in Ham's F-10 (all media and chemicals from Gibco unless otherwise stated) with 1% penicillin-streptomycin solution, 1% fungizone, and 10% foetal bovine serum. The serum had been heated for 1 h at 55°C in the presence of 3% by weight activated charcoal (G-60, Matheson Scientific) and filter sterilised. Steroids were not added for 24 h to avoid any effect the androgens might have on plating efficiency. On day 2 all cultures were changed and androgens were added as designated. The control group received 0.01% carrier ethanol but no added steroids. The androgen-treated cultures received the same medium but with the addition of 8.9×10^{-9} M testosterone or DHT. Thereafter, the culture media were changed every 24 h for 4 d. Any cells floating in the expended media were retrieved by centrifugation and saved for inclusion in the final DNA totals. ^3H -methyl thymidine (^3H -Tdr) (NET-027Z Specific activity 43 Ci mmol $^{-1}$) was added on day 4 directly to the cultures in 0.05 ml of Hanks' balanced salt solution to a final concentration of 0.4 $\mu\text{Ci ml}^{-1}$. After incubation for 2 h the cells were collected by scraping, and washed twice with ice-cold Tris-saline pH 7.4. All centrifugations were at 800g. The cold acid-soluble counts were removed with three 3 ml 10% TCA washes at 0°C . The cells were then incubated at 70°C for 30 min in 0.5 N PCA. After centrifugation a 0.2 ml aliquot was counted for tritium as described in Fig. 2a. DNA analysis was performed by the method of Burton⁶. Probability was calculated using Student's *t* test of means. In all groups five samples were used.

which also contains cytoplasmic and nuclear androgen receptors^{10,11} although Smith *et al.*¹² have described androgen-responsive mammary tumour cells which bind DHT. The cytoplasmic protein in some respects resembles androgen binding protein from other cells but is different from the binding protein found in sera^{4,8}. Furthermore, the steroid binding protein in the DDT₁ cells seems to be involved in the nuclear translocation of testosterone or its metabolites to a nuclear acceptor. Therefore, we conclude that the DDT₁ cell line will prove a useful tool in the search for the mechanism of action of androgens.

This study was supported by grants from the National Institutes of Health and the Ford Foundation. J.S.N. was assisted by a grant from the American Cancer Society. Additional support was obtained from RRB NICHD. We thank Dr Hadley Kirkman for providing the ductus deferens tissue samples.

Serotonin and pituitary-adrenal function

SEVERAL reports have indicated a relationship between the pituitary-adrenal secretion of steroids and brain serotonin (5-hydroxytryptamine) in the rat^{1,2}. Serotonin is believed to be a transmitter or regulator of neuronal function. We have previously investigated the effects of altering brain serotonin concentrations on the daily fluctuation of the pituitary-adrenal system³. We have investigated this problem further, by evaluating the response of the pituitary-adrenal system to a stress stimulus in the rat. Our approach was to either inhibit brain serotonin synthesis with *p*-chlorophenylalanine (PCPA), or to raise the concentration of serotonin with precursors such as tryptophan or 5-hydroxytryptophan (5-HTP)⁴.

We used male Sprague-Dawley rats (150–200 g). They were kept in a 12L:12D environment (lights on at 0700 h) and given food and water *ad libitum*. Serum corticosterone was assayed fluorometrically, while the determination of serum ACTH was made by bioassay⁵. The concentrations of brain serotonin were determined after isolation, using a weak cation exchange resin and fluorometric assay⁶. One hundred and eighty rats divided into two groups were injected intraperitoneally (i.p.) with pyrogen-free saline or PCPA (Pfizer) in saline at a dose of 300 mg kg $^{-1}$ d $^{-1}$.

Daily injections of PCPA for 4 d greatly enhanced and sustained the peak ACTH response to ether stress ($P < 0.05$) (Fig. 1). To assess whether this enhanced response was due to an effect of PCPA on the diurnal variation in

FIG. 1 Time course of the ACTH response to 1 min of ether stress. Each value represents the mean of eight animals. ●, Morning; ■, evening; —, PCPA; ---, saline.

Fig. 2 Effect of serotonin precursors on the ACTH stress response. L-Tryptophan (408 mg kg^{-1}) or 5-HTP alone (212 mg kg^{-1}) or 5-HTP (50 mg kg^{-1}) with the peripheral decarboxylase inhibitor, L- α -hydrazinomethyl-dihydroxyphenylalanine (MK 486; 200 mg kg^{-1}) were injected i.p. into groups of rats (eight per group). The animals were adrenalectomised 24 h before the study to enable us to study the ACTH response isolated from the feedback effects of circulating steroids. The rats were studied 2 h after injection of the serotonin precursors when brain serotonin levels have been reported at maximal levels after the injection of precursors¹¹ and when pituitary adrenal activity has usually returned to normal in control animals after the stress of an injection. Animals were either decapitated and bled at zero time without ether stress or decapitated and bled 2.5 or 15 min after the stress of ether.

the rate of secretion of ACTH in response to stress, the time course of this response to 1 min of ether stress was determined at 0800 h or 2000 h. Figure 1 shows that, whereas in the controls, blood ACTH concentrations after stress peaked at 2.5 min in the morning and at about 15 min in the evening, depletion of serotonin not only enhanced the response, but also greatly altered the rhythm in the response to ether stress; maximum stress response occurred at 10 min, both in the morning and in the evening. Thus, inhibition of brain serotonin synthesis enhanced the stress response, in addition to altering the pattern of the pituitary-adrenal stress response. This agrees with our previous findings that daily injections of PCPA for 2–4 d raised the morning low, and prevented the evening rise in plasma corticosterone in unstressed animals^{1,3}.

Our alternative approach to the study of the role of brain serotonin in the regulation of pituitary-adrenal function was to attempt to raise brain serotonin by the use of the precursors tryptophan (J. T. Baker Co) and 5-HTP (Calbiochem). Tryptophan is the dietary amino acid which is converted to 5-HTP, the immediate precursor of serotonin. We also used a decarboxylase inhibitor (MK-486, Merck, Sharpe and Dohme), which only acts peripherally in combination with 5-HTP to increase brain serotonin levels by inhibiting serotonin formation outside the brain. Adrenalectomised animals (eight per group) were stressed with ether 2 h after the administration of serotonin precursors, and the pattern of the rise in ACTH was studied (Fig. 2). In these adrenalectomised animals, tryptophan increased brain serotonin content by an average of 33%, and significantly reduced the stress-induced secretion of ACTH ($P < 0.01$) which, in the saline controls, occurred by 2.5 min, and returned to prestress levels by 15 min. 5-Hydroxytryptophan alone, or in combination with MK-486, increased brain serotonin content by 2.4-fold and 1.2-fold respectively, and reduced the stress response in these animals significantly ($P < 0.05$). Thus, these precursors of serotonin tended to decrease or inhibit the pituitary-adrenal response to stress. It is interesting that tryptophan which produced an

increase of about 33% in brain serotonin had a greater effect on ACTH than 5-HTP, which produced a much greater increase. This is consistent with the conclusion of Moir and Eccleston that tryptophan loading is the more physiological method of increasing brain serotonin content⁷.

Preliminary reports on human studies also appear to support this serotonin pituitary-adrenal interrelationship. 5-Hydroxytryptophan seems to reduce the 24 h excretion of 17-hydroxycorticosteroids in human volunteers^{3,8}.

It is now reasonably well accepted that the pituitary-adrenal system functions as a closed loop. In this system, the positive vector or 'driving force' corresponds to environmental stimuli, acting through hypothalamic neuro-humoral pathways⁹ and the negative vector corresponds to the concentration of corticosteroids which act by feedback inhibition on the pituitary-adrenal system¹⁰. We found that the stress response was enhanced by inhibition of serotonin synthesis, and found indications of a reduction of the stress response by serotonin precursors. This suggests that serotonin may mediate or modulate this negative feedback mechanism regulating pituitary-adrenal function.

If this hypothesis were correct, then the inhibitory action of corticosteroids on steroid output would be expected to be less effective in animals in which brain serotonin was depleted. Figure 3 illustrates the results of an experiment testing this possibility, and compares the corticosterone stress response inhibiting properties of two doses of a steroid (prednisolone) in control rats and in animals whose brain serotonin content was markedly reduced by pretreatment with PCPA. Both doses of the steroid effectively inhibited the response to the stress of ether and laparotomy in the control animals. In serotonin-depleted animals, neither dose was capable of blocking the stress response, further indicating that serotonin is indeed involved in the negative feedback to the pituitary-adrenal system.

These results, taken together, lead us to speculate that in some disease states, such as Cushing's syndrome, where there is a similar inability of corticosteroid to suppress the pituitary-adrenal system, there is a defect in serotonergic neuronal processes that impairs pituitary-adrenal feedback mechanisms. Thus, we reason that serotonin precursors may be useful as a diagnostic screening test to identify cases of Cushing's syndrome with the postulated serotonergic defect. Further, serotonin precursors (tryptophan or 5-HTP, with

Fig. 3 The effect of serotonin depletion on the inhibition of corticosterone release by prednisolone. Groups of rats (eight per group) were stressed with ether and laparotomy 24 h after two daily injections of PCPA ($300 \text{ mg kg}^{-1} \text{ d}^{-1}$ i.p.) or saline and 4 h after the injection of the steroid (1.25 mg or 5.0 mg per 100 g body weight subcutaneously). Brain serotonin concentrations were determined on the unstressed group of rats. Open columns, unstressed; hatched columns, 15 min after ether laparotomy stress.

or without a peripheral decarboxylase inhibitor), or agents which stimulate serotonin receptors, may be useful in the therapy of some forms of Cushing's disease.

This work was supported principally by a grant from The Grant Foundation, and in part by the Public Health Service and NASA. J. D. B. holds a Career Scientist Development Award. We thank Merck, Sharpe and Dohme for PCPA and Armour for ACTH standard.

Unresponsiveness of human B lymphocytes to phytohaemagglutinin

A WIDELY accepted, but unproven, distinction between human T (thymus-derived) and B (non-thymus-derived) lymphocytes is their differential response to mitogenic stimulation with phytohaemagglutinin (PHA). It has been claimed that such a distinction does not truly exist and that the human B cell, unlike the murine B cell, transforms in the presence of PHA¹. An editorial² commenting on the consequences of this claim appropriately emphasised the danger of extrapolating data from one species to another. This communication presents evidence that pure populations of human B cells do not transform in response to stimulation with PHA. It also stresses the need of reducing the contamination of B cell preparations by T cells when studying the *in vitro* behaviour of the human B lymphocytes.

Pure populations of human T and B lymphocytes were obtained from tonsils using a two-step fractionation procedure. Cells were first fractionated on discontinuous gradients of bovine serum albumin (BSA)³ and then separated on the basis of their reactivity with the sheep red cell intermediates E and EAC1423 (EAC3) (Fig. 1).

Tonsil cells sedimenting in fraction 4 of the BSA gradient (interface of 23 and 25% BSA) were enriched in T cells. Forty to fifty per cent of the cells in fraction 4 formed rosettes with E (Fig. 1b), and only 15–20% reacted with EAC3 and stained with fluorescent antisera to human immunoglobulins (Fig. 1c, d). Cells sedimenting in fraction 7 of the BSA gradient (interface of 29 and 31% BSA) were almost exclusively B cells. Ninety to ninety-five per cent of

the cells in this fraction reacted with both EAC3 and fluorescent antisera to human immunoglobulins (Fig. 1c, d), and fewer than 5% formed rosettes with E (Fig. 1b).

B cells were obtained by taking the E non-rosette-forming cells from fraction 7. Ninety-eight to one hundred per cent of these cells exhibited reactivity with EAC3 and surface staining with fluorescent antisera to human immunoglobulins. Less than 2% of these cells formed rosettes with E on retesting (Table 1). T cells were obtained by taking either the

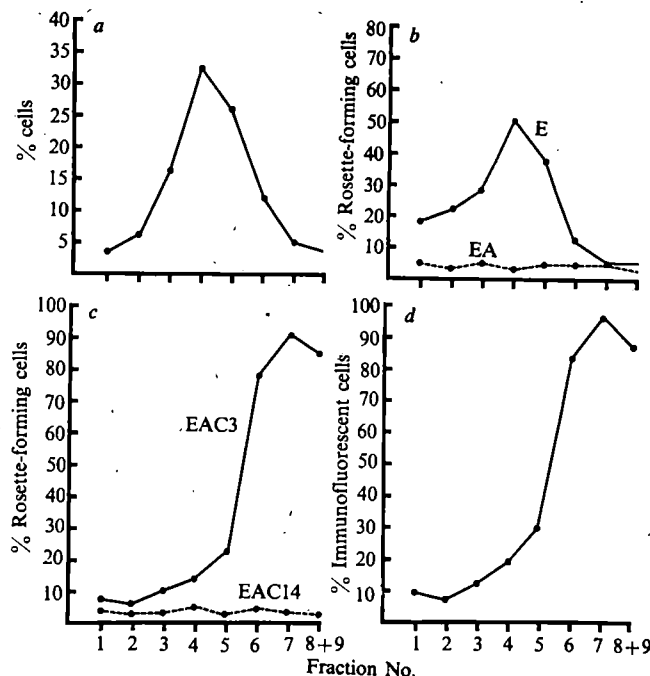

FIG. 1 *In vitro* response of tonsil lymphocytes separated into nine fractions by centrifugation in a discontinuous gradient of 17–35% BSA. a, Relative distribution of lymphocytes after purification by passage through glass beads. b, Rosette formation with sheep erythrocytes (E) compared to EA as a control. c, Rosette formation with EAC3 compared to EAC14 (control). d, Percentage of cells staining with antisera to human immunoglobulins. Values represent the average of four experiments. Human tonsils were teased in Medium 199 (Microbiological Associates), and the resulting suspensions were passed through columns of glass beads at 37° C to remove adherent cells. Column eluates contained more than 90% viable lymphocytes as determined by trypan blue exclusion. Cells in the eluate were fractionated on discontinuous gradients of BSA by a modification of the method of Dicke *et al.*³. Cells from each fraction were washed in Medium 199, then tested for their ability to form rosettes with the sheep red cell intermediates E and EAC1423, as well as for surface staining with fluorescent antisera to human immunoglobulins. Red cell intermediates E, EA, and EAC14 were prepared using human components of complement and were suspended at a concentration of 1% in phosphate-buffered saline (PBS). Lymphocyte suspensions were adjusted at 2×10^6 cells ml⁻¹ in PBS containing 10% serum from a donor with type AB Rh⁺ erythrocytes and absorbed three times with sheep erythrocytes. Equal volumes of lymphocyte and E or E-intermediate suspensions were mixed. Tubes containing E and EA were incubated for 30 min at room temperature, while those containing EAC3 and EAC14 were incubated for the same period of time at 37° C. Following this initial incubation, all tubes were centrifuged at 200g for 4 min at 4° C, and the pellets were incubated at 4° C for 1 h. Cells were then resuspended and examined microscopically, and the percent of rosette-forming cells determined. Lymphocytes intimately associated with four or more red cells were considered to have formed rosettes. Immunofluorescence was performed using fluorescein-conjugated antisera raised in goats against human IgG, IgM, and IgA myeloma proteins. Each antiserum was rendered monospecific for the heavy chain of a single class of immunoglobulins by absorption on suitable antigens coupled to Sepharose 4B by cyanogen bromide.

E rosette-forming cells or the EAC3 non-rosette forming cells from fraction 4. T cell preparations contained less than 5% EAC3-reactive immunofluorescent staining cells (Table 1).

B cells uniformly failed to transform in response to stimulation with PHA; stimulation index (s.i.) = 2 (Table 2). PHA caused vigorous proliferation of T cells with s.i. ranging from 57 to 166 (Table 2). The unresponsiveness of the B cell to PHA could not have been due to cell death. Viability of B cells after 72 h in culture always exceeded 65% as determined by trypan blue exclusion, and parallel B cell cultures always transformed normally in response to pokeweed mitogen (PWM) added at a concentration of 1/100 (s.i. 4-11).

Lack of adherent cells was ruled out as a cause for the unresponsiveness of the B cell cultures to PHA. Adherent cells, T cells, and B cells were prepared from the same tonsil. In combination experiments, 1×10^5 to 2×10^5 adherent cells were added to 1×10^6 B or T cells. The results in Table 2 show that the addition of adherent cells did not affect the response of the B cell to PHA, but increased the mitogenic response of the T cell to PHA. Adherent cells by themselves did not transform in response to PHA.

The effect of the contamination of purified B cell cultures by T cells on the PHA response was studied. Five per cent (5×10^5) T cells were mixed with 95% (95×10^5) B cells from the same donor. The overall response of the mixture to PHA was found to exceed by far the sum of the responses of the individual T and B cell components (Table 2). This effect was not seen when either one of the two components was previously subjected to irradiation with 7,000 r.

An attempt was made to determine if this enhancing effect was due to the action of a soluble mediator released by T cells and acting on B cells. The results in Table 3 show that supernatants from resting T cells, as well as supernatants from PHA-activated T cells, failed to cause transformation in B cells. T cells proliferated more vigorously in the presence of the PHA-containing supernatants than in the presence of PHA alone (Table 3).

That human B cells fail to transform with PHA was also shown by studying lymphocytes from a 6-month-old boy with the diagnosis of severe combined immunodeficiency. These lymphocytes exhibited characteristics of B cells; 3% formed rosettes with E; 95% showed immunofluorescence with an anti- μ -chain antiserum. Stimulation indices of 1.9 and 2.0 with PHA and 7.5 and 9.1 with PWM were obtained when these cells were cultivated *in vitro*.

The data presented here regarding the human B cell response to PHA are in agreement with those on B cells from

TABLE 2 Proliferative response of human B, T and adherent cells to PHA

Cells in culture	³ H-Thymidine incorporated per culture		s.i.
	Without PHA c.p.m.	With PHA c.p.m.	
1×10^6 B cells	1,011	1,332	1.3
1×10^6 T cells	864	96,722	112.0
1×10^6 adh cells	1,235	967	0.8
1×10^6 B cells + 1×10^5 adh cells	1,174	1,305	1.1
1×10^6 T cells + 1×10^5 adh cells	908	117,460	129.0
5×10^5 T cells	385	17,033	44.2
95×10^5 B cells	1,158	1,388	1.2
5×10^5 T cells + 95×10^5 B cells	1,147	38,565	33.6

Lymphocytes were cultured at a final concentration of 1×10^6 cells ml^{-1} in Medium RPMI-1640 (Grand Island Biological Company) supplemented with 15% serum obtained from an individual with AB Rh⁺ erythrocytes and containing penicillin ($50 \mu\text{g ml}^{-1}$), streptomycin ($50 \mu\text{g ml}^{-1}$), kanamycin ($50 \mu\text{g ml}^{-1}$), and mycostatin ($50 \mu\text{g ml}^{-1}$). Duplicate 1 ml cultures were set up in 12×75 mm Falcon plastic tubes and incubated in a humidified atmosphere of 5% CO_2 in air. Phytohaemagglutinin (PHA-P, Difco) was added at a final concentration of 1:100. Seventy-two hours after the onset of incubation, cultures were pulsed with ³H-thymidine (1.9 Ci mmol^{-1} , $1 \mu\text{Ci ml}^{-1}$; New England Nuclear). Sixteen hours later, cultures were collected and the amount of ³H-thymidine incorporated into DNA was determined by the filter paper disk technique³. Results were expressed as c.p.m. incorporated per culture and as stimulation indices (s.i.) where

$$\text{s.i.} = \frac{(\text{c.p.m. of } ^3\text{H-thymidine incorporated by the stimulated culture})}{(\text{c.p.m. of } ^3\text{H-thymidine incorporated by the unstimulated culture})}$$

Adherent (adh) cells from tonsils were prepared by fractionating aliquots of single cell suspensions on BSA gradients without previous passage over glass beads. Fraction 3 of such gradients was enriched in monocytes (30-40%), determined by their ability to stain with neutral red. Cells from fraction 3 were reacted with E, after which the E non-rosette-forming cells were separated over a Ficoll gradient, washed, and resuspended at a concentration of $3 \times 10^7 \text{ ml}^{-1}$ in Medium 199, supplemented with 30% AB Rh⁺ human serum. Five millilitre aliquots of this cell suspension were added to 100 mm Petri dishes. Dishes were incubated at 37°C for 30 min, rocked gently for 5 min, and washed with 10 ml of M199. The rocking and washing step was repeated five times. Cells remaining adherent to the bottom of the dish at the end of the washing procedure were collected with a rubber policeman, washed, and resuspended in culture medium at a concentration of 1×10^6 cells ml^{-1} . Eighty to ninety per cent of the cells in this adherent cell preparation stained with neutral red. Identical results to those shown in the Table were obtained in four different experiments.

other species like the mouse, guinea pig, and chicken⁴⁻⁷. Our data, however, are in conflict with those of Phillips and Roitt¹, who used human B cell preparations in which at least 10% of the cells were non-B cells.

It seems that in man, as in the mouse, though pure B cells do not transform with PHA, a mixture of 5% T cells and 95% B cells exhibits a strong proliferative response to PHA which exceeds the sum of the responses of the individual T and B cell components⁸. In the mouse, karyotypic analyses of such mixtures revealed that by day 2 of culture 35% of the observed mitoses were B cells and that by day 3 of culture 97% of the mitoses were B cells. Similar data are not available for human cells.

The more-than-additive PHA response of human T and B cell mixtures could not be attributed to a soluble mediator released by T cells and acting on B cells. Human B lymphocytes, like chicken B lymphocytes, failed to proliferate in the presence of supernatants obtained from PHA-activated T cells⁷. But, in the case of *in vitro* stimulation with antigen to which cell donors are immune, it was found that the human B cell does not transform with antigen alone but transforms

TABLE 1 Characteristics of B and T lymphocyte preparations from human tonsils

Cell Source	T Lymphocytes*	B Lymphocytes†
E (+)	>95%	< 2%
EAC3 (+)	< 5%	>98-99%
Immunofluorescent (+)	< 5%	>98-100%

* E-reactive cells from fraction 4 of the BSA gradient

† E non-reactive cells from fraction 7 of the BSA gradient

Cells from fractions 4 and 7 of the BSA gradient were reacted with E or EAC3, and the lymphocyte sheep red cell mixtures were layered on top of Ficoll-Hypaque gradients and centrifuged at 400 g and 18°C for 45 min. Non-rosette-forming cells collected at the interface of the gradient, while rosette-forming cells and red cells collected at the bottom of the gradient. Cells collected from the bottom of the gradient were treated for 10 min with 0.87% NH_4Cl to lyse the red cells. Lymphocytes collected from the Ficoll gradient were washed three times in Medium 199 before culture. Cell recovery, following Ficoll gradient separation, averaged 70-80%. Viability of the recovered cells always exceeded 90%.

TABLE 3 Effect of T cell supernatants on proliferative response of human B and T cells to PHA

Addition to culture	³ H-Thymidine incorporated per culture of	
	B cells	T cells
None	c.p.m. 925	c.p.m. 812
PHA	1,067 (1.1)	82,638 (101)
24-h supernatant from T cells	877 (0.9)	763 (0.9)
24-h supernatant from T cells + PHA	1,168 (1.3)	78,314 (96.4)
24-h supernatant from PHA-activated T cells	1,309 (1.4)	98,561 (120)
48-h supernatant from PHA-activated T cells	993 (1.1)	91,426 (113)

Supernatants were derived from cultures of T cells incubated at 1×10^7 cells ml⁻¹ with or without PHA. Culture supernatants were filtered through 0.45 μ m filters (Millipore Corporation, Bedford, Massachusetts) and stored at -20° C until tested. Supernatants were added at 1:2 dilution to both B and T cells cultures. PHA concentration was adjusted to 1/100 in all cultures. Identical results were obtained in four different experiments. Values in between parentheses represent s.i.

vigorously (s.i. 20-40) in the presence of supernatants derived from antigen-activated T cells⁹. In the process, the B cell loses its C3 receptor, accumulates rough endoplasmic reticulum, and engages in antibody secretion. If the human B cell transforms with PHA only in the presence of T cells, then this could mean that intimate B cell to T cell contact is needed. It would be interesting to know if human B cells, like their murine counterparts, possess receptors for PHA as T cells but do not respond to the mitogen¹⁰ or if they lack a receptor for PHA.

It is clear from this work that it is necessary when studying the behaviour of the human B lymphocytes to reduce as much as possible contamination of the purified B cell preparations with T cells. Caution should also be exercised in extrapolating data from mouse to man, as the B cells from the two species have been recently shown to behave differently *in vitro* in response to stimulation with phytohemagglutinins, antigens, and lipopolysaccharides (R.S.G. and E.M., unpublished).

We thank Miss Elizabeth Preisig for technical assistance, Dr Harvey Colten for providing the sheep red cell intermediates, and Dr John Gaten for providing the immunofluorescent antisera. This investigation was supported by a US. Public Health Services grant. R. S. G. is a recipient of a postdoctoral fellowship from the Lebanese Research Council and of a US Public Health Service International Fellowship.

Independent behaviour of blood group A- and B-like activities in gastric carcinomata of blood group AB individuals

SIMMONS and Perlmann¹ have provided evidence that the carcinoembryonic antigen (CEA) (ref. 2) is an incomplete blood group substance that lacks the type 1 chain in most of the material studied. This deficiency was explained by deletion or repression in gastrointestinal carcinomata of genes and related transferases required for the synthesis of the blood group specific macromolecules. The chains which are not incorporated apparently accumulate as suggested by the work of Hakomori *et al.*³. Since A-, B-, H-, and Le^a-specific sequences in the type 2 chain were also missing in the CEA preparations¹ Simmons and Perlmann concluded that gastrointestinal adenocarcinomata may, in addition, have more specific defects localised at the ABO, H, and Le loci. Morphological studies dealing with the distribution of blood group-like antigens in carcinomata⁴⁻⁹ have provided further proof for the disturbance of the synthesis of blood group substance in neoplasia. Davidsohn⁶ reported a correlation between the histological degree of differentiation of the tumour and the presence of blood group substance and suggested an inverse relationship between the ability of a tumour to produce blood group substance and to metastasise. In the course of morphological studies dealing with the relationship between blood group substance and CEA in tumour tissue, we studied five specimens of surgically removed gastric carcinomata from patients with the blood group A₁B and we observed independent behaviour of the A and the B specificity in four of them in certain areas of the malignant growth.

The specimens were fixed in neutral buffered formalin, embedded in paraffin and subsequently treated for the demonstration of blood group antigens by the modified mixed cell agglutination reaction (MCAR)¹⁰ as described by Davidsohn (for review see ref. 6). Commercial antisera to blood group substance (BG)-A and -B (Ortho) were concentrated to a haemagglutination titre of approximately 1:500.

FIG. 1 Moderately differentiated gastric adenocarcinoma. a, Positive MCAR (BG-B); b, negative MCAR (BG-A). Serial sections. $\times 285$, Haematoxylin and eosin (HE).

TABLE 1 A and B blood group substance—like activity in gastric cancer tissue of patients with blood group AB

No.	11027	14283	1899	1896	2878

Signet ring cell carcinoma	—	—	—	A neg/B neg	A neg/B neg

Ulex europaeus extracts were used to detect H activity. According to ref. 6 blood group substances soluble in both water and alcohol are preserved during formalin fixation and paraffin embedding. After completion of the specific red cell adherence reaction the specimens were fixed in 1–5% glutaraldehyde and stained with haematoxylin-eosin. Histologically the tumours showed a variety of patterns from rather well-differentiated adenocarcinoma to anaplastic globocellular growth. Signet ring cells were present in two carcinomas. The normal superficial as well as the intestinal metaplastic mucosa were rich in both BG-A and BG-B in all of our five cases in a distribution typical for secretors^{11,12}. The endothelial cells of the blood vessels and the erythrocytes in the normal tissue as well as within the carcinoma were positive with respect to BG-A and BG-B in every case thus providing appropriate positive controls. Reagent controls were non-isologous antiserum and isologous indicator erythrocytes and *vice versa*. No relationship between the presence of blood group substances and the histological degree of differentiation was observed in our cases and different distribution patterns of BG-A and -B activities were observed even in morphologically identical areas (Table 1). No H activity was demonstrable in the tumours although control specimens of blood group O and A₂ gave positive results with the *Ulex* extract used.

CEA was postulated to result from defective synthesis of blood group substances in gastrointestinal carcinomata

FIG. 2 Moderately differentiated gastric adenocarcinoma (same tumour as in Fig. 1). Negative MCAR for BG-B (shown) as well as for BG-A (not shown) in the tumour. Positive reaction in adjacent normal mucosa (1) and vessel (2). $\times 400$, HE.

due to genetic defects¹. Our results allow us to localise possible genetic defects more precisely. α -N-acetyl-D-galactosaminyl transferase and α -D-galactosyl transferase, respectively, that attach the appropriate sugars in 1 \rightarrow 3 linkage to the β -galactosyl unit in an H-active structure depend upon intact A and B genes, respectively¹³. Since these transferases have identical acceptor substrate requirements¹³ the selective loss of either BG-A or BG-B is most likely to be due to deletion or repression of the corresponding gene (either A or B) in the ABO locus. A similar mechanism was discussed to explain the appearance of A₂, A₂B, B and O erythrocytes in a patient with leukaemia¹⁴. Disappearance

of both A and B blood group substances in other parts of the same carcinoma confirms that the genetic and related enzyme defects vary even in the same tumour. The exact relationship between blood group substances and CEA in cancer tissue is not yet established. Different degrees of genetically determined lesions are conceivable: selective loss of one antigenic specificity may represent the minimal change in a process that leads to the development of a CEA-specific chemical structure.

Other, less likely explanations of the selective loss of one BG specificity in A,B patients should also be considered. One is the absence of substrates such as N-acetyl-D-galactosamine or D-galactose in the tumour. This possibility is unlikely since the intact precursor molecule relies on the presence of these carbohydrates. It is also possible that a specific A- or B-destroying enzyme exists in the tumour cells.

Model for the binding of multivalent antigen to cells

It has been suggested frequently¹⁻⁴ that antigen must be presented to immunocompetent cells in multivalent or aggregated form in order to stimulate the cells to proliferate and secrete antibodies or otherwise respond. Multivalent antigens, that is antigen molecules with more than one identical epitope per molecule, seem to bind multivalently and irreversibly to the antibody-like receptors on immunocompetent cells^{5,6}, and T cells or their products may serve to aggregate antigen molecules so as to present them to other cells in multivalent forms⁷. The binding of multivalent ligands to lymphocyte receptors is known to induce receptor-ligand lattice formation and in many cases to induce mitosis and antibody secretion from B cells^{4,8,9}.

It is also known that, after exposure of an animal to antigen, the affinity of the antibodies which are produced will often increase with time^{10,11}. This maturation of the immune response could be understood^{12,13} easily if the binding of antigen to cells and cell proliferation were governed by the equilibrium constant for receptor (antibody)-epitope

binding. A small (and decreasing) concentration of free antigen would then bind cells with high (and increasing) affinity receptors and would selectively stimulate such high affinity cells. If, however, the antigen-to-cell binding is actually multivalent and irreversible⁶, it is not clear how it can be determined by the receptor-epitope equilibrium constant, and consequently how the maturation can be induced.

The purpose of this communication is to present a simple model of how the rate of multivalent and irreversible binding can be governed by an equilibrium constant for epitope-receptor binding. Although the model is highly simplified, it suggests several testable relationships between important measurable quantities.

The model is depicted in Fig. 1. Consider a mixture of multivalent antigen molecules and cells to which they can bind. In binding to a cell, an antigen molecule is assumed first to bind to a single receptor at one binding site with rate constant k_a . From this configuration the antigen molecule can either dissociate with rate constant k_d or form a bond with another receptor molecule, with rate constant k_i , thereby establishing multivalent and irreversible binding. We ignore, or alternatively, include in k_d ¹⁴, the binding of one antigen molecule to two sites on the same receptor molecule.

Let c be the concentration of free antigen, ρ and ρ_0 be the concentrations of free and total receptor sites, m be the concentration of singly bound antigen molecules, and M be the concentration of multiply bound antigen molecules, with on the average n bonds per molecule. Then the equations of the model are

$$\rho(t) = \rho_0 - m(t) - nM(t) \quad (1)$$

$$\frac{dm}{dt} = k_a c \rho - k_d m - k_i m \rho \quad (2)$$

$$\frac{dM}{dt} = k_i m \rho \quad (3)$$

Different cells may have different values of k_a , k_d , k_i , and ρ_0 . We assume that the reversible binding is near equilibrium so that as a first approximation we set $dm/dt = 0$ in equation (2) to obtain,

$$k_a c \rho = k_d m + k_i \rho m \quad (4)$$

Two limits can be considered.

(1) If $k_d \ll k_i \rho$, the dissociation rate is slow compared with the rate of establishing multivalent binding. Then from equation (4) $k_i \rho m \approx k_a c \rho$ and substituting in equation (3)

$$\frac{dM}{dt} = k_a c \rho. \quad (5)$$

In this limit, as soon as a first bond is established subsequent bonds will be established. The rate-limiting step is first bond formation. The various antigen binding cells will differ somewhat in their values of k_a , and perhaps ρ_0 , but variation in the epitope-receptor equilibrium constant, $K \equiv k_a/k_d$, is expected^{14,15} to be primarily due to variation in k_d , not in k_a . Therefore in this limit we do not have a mechanism for preferentially binding to and selecting cells based on their equilibrium binding.

(2) If $k_d \gg k_i \rho$, the dissociation rate is rapid compared with the rate to establish multiple bonds. Then equation (4) gives $m = Kc\rho$. With equation (1) this gives

$$\rho = \frac{\rho_0 - nM}{1 + Kc}, \quad m = \frac{Kc}{1 + Kc} (\rho_0 - nM) \quad (6)$$

so that equation (4) becomes

$$\frac{dM}{dt} = k_i \frac{Kc}{(1 + Kc)^2} (\rho_0 - nM)^2. \quad (7)$$

FIG. 1 Multivalent antigen is assumed first to combine reversibly with a cell receptor, with forward and reverse rate constants k_a and k_d , and then irreversible binding is established to further receptors with rate constant k_i .

In this limit, the times for both first and second bond formation are important, and the rate of establishing multivalent binding is proportional to $Kc/(1 + Kc)^2$. For cells with small values of K (that is, $K \ll 1/c$), the rate is slow because few receptors have (singly bound) antigen molecules stuck to them. If any cells have such large values of K that $K \gg 1/c$, they will also have slow rates of multivalent binding because most receptors are already singly bound to antigen molecules and therefore unavailable for establishing multiple bonds.

Equation (7) suggests a simple model for maturation of immune responses when irreversible multivalent binding of antigen is required for cell stimulation. In particular, assume that the rate of establishing multivalent binding must exceed some value, $1/T$, in order for the cells to be stimulated. Here T is a time which might be the natural lifetime of immunoglobulin receptors on cell surfaces^{16,17}. If the maximum value of the relative rate, $\rho_0^{-1} dM/dt$, must exceed $1/T$, we obtain from equation (7)

$$k_i \rho_0 \frac{Kc}{(1 + Kc)^2} > \frac{1}{T} \quad (8)$$

Only cells with K values such that the criteria of equation (8) are satisfied would be stimulated by a free antigen concentration, c . This equation is very similar to some^{12,13} which were derived for (monovalent) equilibrium binding and which gave maturation kinetics in reasonable agreement with experiment. In these studies¹³, high zone tolerance was postulated (*ad hoc*) in that cells with large values of Kc were not stimulated and were sometimes assumed to be killed. Equation (8) clearly predicts that cells with sufficiently high values of Kc will not be stimulated.

Equation (7) can be solved readily. If antigen is first introduced at $t = 0$ and c is thereafter constant, the solution is

$$M = \left[\frac{\rho_0}{n} \frac{\alpha \rho_0 t}{1 + \alpha \rho_0 t} \right] \quad (9)$$

where $\alpha \equiv nk_i Kc/(1 + Kc)^2$.

Which limit is more likely to apply? For the dissociation of haptens or small antigens from antibodies, k_d is typically¹⁵ 1–100 s⁻¹, so that we assume that for antigen bound to a receptor at one site, typically $k_d \gg 1$ s⁻¹. For those antigens that can rapidly establish a double bond to one receptor molecule, k_d is much smaller, perhaps typically¹⁴ $\sim 10^{-3}$ s⁻¹. The rate $k_i \rho_0$ to establish a bond to a second receptor molecule will depend on the diffusion of receptors in the membrane and has been estimated to be¹⁸

$$k_i \rho_0 = an t_D^{-1} \equiv an \frac{D}{d^2} \quad (10)$$

where d is the mean spacing between receptor molecules ($d \simeq 40$ nm for B cells¹⁸), D is the receptor diffusion coefficient¹⁹ ($D \gtrsim 5 \times 10^{-11}$ cm² s⁻¹), nt_D^{-1} is a diffusion limit to the reaction rate and a is the factor by which the actual rate differs from the diffusion limit. For $an \simeq 0.01$, $k_i \rho_0 \gtrsim 0.03$ s⁻¹. We therefore conclude that for antigens which bind to only one site on a receptor molecule, limit

(2) and equation (7) may apply, while for antigens which bind easily to two sites on a receptor molecule, limit (1) and equation (5) probably apply. The precise configuration of epitope binding sites on receptors is not known and it is possible that for some kinds of cells, only one site per receptor molecule may be accessible for binding antigen. It is known that contact with antigen can modulate the number of cell receptors, but such refinements are ignored in the present model.

The model suggests that to achieve response maturation together with multivalent binding, the condition

$$k_d > an \frac{D}{d^2} \quad (11)$$

should be satisfied. Maturation is therefore favoured by (1) large k_d , that is, rapid release of initially bound antigen such as is expected for binding to a single site on the receptor molecule, (2) small D , that is, sluggish diffusion of receptor molecules, (3) large d , that is, large spacing and small density of receptors, and (4) small antigen valence, n . These three first factors may differ between various cell classes, such as T and B cells, or between different stages in cell maturation. There is some evidence²⁰ that cells in an IgM response may not mature whereas those in an IgG response do mature. If so, the model suggests that the cells which are proliferating in IgM(IgG) responses do not (do) meet equation (11). During maturation, a clone might switch from IgM to IgG production and begin to meet equation (11) by changing the number, mobility or accessibility of its receptors.

This model indicates some simple ways in which receptor properties may affect the kinetics of antigen binding to cells and cell behaviour. It also suggests the importance of quantitative measurements of receptor number and mobility and of antigen-to-cell binding kinetics in elucidating the mechanisms which operate in antigen selection of clones, either for amplification or suppression.

Localisation of sites of GABA catabolism in the rat retina

GAMMA aminobutyric acid (GABA) has been demonstrated in invertebrate and vertebrate retinæ^{1,2,3} and has been shown to have an inhibitory action on retinal neurones⁴. *In vivo* studies of ³H-GABA uptake by rabbit retina have shown a distribution of radioactivity in the inner plexiform layer, the amacrine cells of the inner nuclear layer, the ganglion cell and nerve fibre layers⁵. Further studies have shown that all layers of the rat retina except the outer zone of the rods will accumulate ³H-GABA *in vitro*⁶ in the presence of amino-oxyacetic acid (AOAA), an inhibitor of GABA metabolism⁷. Uptake was most pronounced in the ganglion cell and nerve fibre layer, inner nuclear and outer plexiform layers and at the outer limiting membrane. Furthermore, it was suggested that ³H-GABA might be largely taken up by Müller's fibres and their nuclei rather than by amacrine cells in the inner nuclear layer of the retina.

Other reports have described sites of enzyme activities involved in GABA metabolism in the retina. Glutamate decarboxylase (GAD) was unevenly distributed across the six well-defined layers of the dark-adapted frog retina³ and in layers of the rabbit retina¹. GABA-transaminase (GABA-T) was present in the frog retina in both the light and dark adapted states² although attempts to localise GABA-T at the cellular level in the rabbit retina were unsuccessful¹.

Previous studies have shown the ability of retinal cells to accumulate ³H-GABA, the presence of a GABA-synthesising enzyme (GAD) and correlative amounts of its product in retinal cells¹. If GABA were involved in inhibitory transmission in the retina⁴, there would be a requirement for a GABA-degradatory process. The present histochemical study investigates the localisation of the GABA-degrading enzyme GABA-T in the rat retina.

Intact eyes from adult (250–300 g) Sprague-Dawley rats were removed under ether anaesthesia, embedded in supporting tissue on microtome chucks and quenched in liquid nitrogen; preliminary studies indicated that there was no contamination from the embedding tissue. The chucks were placed in a cryostat compartment and after equilibrium at –18° C, unfixed sections were cut at 12 µm, mounted onto glass slides and freeze dried over activated silica gel at –20° C for a minimum of 3 h. GABA-T activity was demonstrated by a previously described dehydrogenase/tetrazolium-coupled system^{8,9}. In control studies tissue sections incubated with all components except GABA produced a very faint reaction only after extended incubation, which was probably due to NADH₂ diaphorase, an integral part of any tetrazolium-linked system. Sections incubated without α-ketoglutarate also showed a very weak reaction after extended incubation but an intense well-localised formazan precipitate was only seen when all substrate components of the incubation medium (GABA, α-ketoglutarate, NAD⁺) were included. The specificity of this method has been described elsewhere⁸. Routine Ehrlich's haematoxylin and eosin stains were carried out on alternate sections in order to identify the retinal layers.

Light microscopic examination after 30 min incubation revealed that a reaction was mainly present in the ganglion cell and inner plexiform layers, the inner nuclear and photoreceptor layers and the pigment cell layer. The reaction was absent in cells of the outer nuclear layer and in the outer and inner limiting membranes (Fig. 1a). The moderate reaction in the cytoplasm of the ganglion cells of the ganglion cell layer was similar to the reaction seen in the neuroglia in this layer. The strong reaction in the inner plexiform layer corresponded to the site of synapses between bipolar and amacrine cells and the ganglion cells. Some cells of the inner nuclear layer exhibited a good reaction, however, comparison of this stained layer with an H and E stain (Fig. 1b) showed that not all cells in the inner nuclear layer showed the enzyme

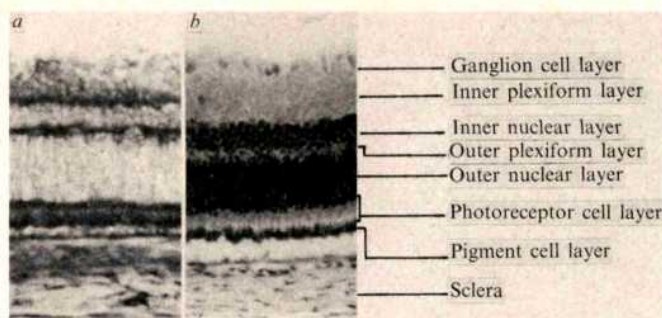

Fig. 1(a), Sites of the GABA-degrading enzymes GABA-T in transverse section of rat retina. Note reaction in the ganglion cell layer, inner plexiform layer, inner nuclear layer and photoreceptor layer (X357). (b), Transverse section of rat retina. Ehrlich's haematoxylin and eosin stain (X357).

activity. A reaction in cells of the outer zone, comprising mostly of horizontal cells, was absent. The reaction was also absent in the bipolar cells of the outer intermediate zone. However, a strong reaction was seen in the zones containing the cell bodies of Müller's fibres (inner intermediate zone) and the amacrine cells (inner zone) (Fig. 2). A reaction was seen in the sustentacular fibres of Müller which extended through the retinal layers between the outer limiting membrane and the ganglion cell layer; the reaction was clearly defined where the fibres terminated in large conical expansions at the vitreal aspect (Fig. 2).

No reaction was seen in the outer plexiform layer at the site of synapses between the rod and cone cells and the bipolar cells. An intense reaction was seen in the inner zone of the photoreceptor layer outside the outer limiting membrane, and in a thin layer of rod and cone cell bodies immediately adjacent to the vitreal aspect of the outer limiting membrane. The reaction was weak in the outer zone of the photoreceptor layer. The epithelial cells of the pigment cell layer and cells of the sclera exhibited a moderate reaction.

Information has accumulated to indicate that the retina possesses a high affinity active uptake system for GABA^{10,11}. It has been suggested that besides uptake and storage of ³H-GABA by 'GABA-neurones'¹⁰ this system also exists for the removal of GABA from retinal neurones or the neuronal environment after release from inhibitory nerve endings¹¹. Other data indicate that the Müller gliocytes of the retina may be largely responsible for inactivation of GABA by this uptake process^{3,6}. We propose that Müller gliocytes are also responsible for the degradation of GABA, which occurs in these cells after GABA uptake and is indicated by high levels of GABA-T activity in Müller cell bodies and fibres running radially throughout the retina. In support of this, intravitreal injection of ³H-GABA failed to produce labelling of Müller cells *in vivo* 4 to 12 h after injection⁵, probably due to catabolism of GABA by the high GABA-T activity now demonstrated in Müller's cells. Inhibition of retinal GABA-T by AOAA however potentiates accumulation of ³H-GABA in the retina⁷, especially in Müller's cells⁶. This strongly suggests that these glial cells are partly responsible for the uptake and degradation of GABA in the retina and that GABA is not stored after *in vivo* uptake into these cells.

Although amacrine cells possess high levels of GABA-T activity they also accumulate ³H-GABA *in vivo*^{5,10} unlike Müller gliocytes. This suggests that a protective store for GABA exists in the amacrine cells; a protective store for GABA is believed to occur in some retinal neurones¹². In this way, GABA is stored for liberation during neuronal activity, possibly during inhibitory action on ganglion cells (for refs see ref. 10). The presence of GABA-T in amacrine cells may act as a limiting factor on GABA storage, although the process for this is obscure and cannot be shown by this study.

An uneven distribution of endogenous GABA, ^3H -GABA uptake, GAD activity^{1,3,5,6,10} and GABA-T activity in the retina has been demonstrated. Within the inner plexiform layer there are high levels of GAD and GABA-T activity. GAD activity is thought to be located predominantly in amacrine nerve endings³ suggesting that the amacrine may be the main GABA synthesising cells of the retina. From present data, GABA-T activity is thought to be localised essentially in the meshwork of Müller's fibres and associated fibrillae which surround the synapses of the inner plexiform layer and not in the synapses themselves. Light microscopy cannot completely resolve this feature but the conclusion is supported by the observation that GABA-T activity in Müller's fibres increases in areas corresponding to synaptic regions, where the fibres pass through the inner plexiform layer.

The presence of high levels of GABA-T activity in the inner zones of the photoreceptor layer and in a thin layer of rod and cone cell bodies at the outer limiting membrane is also intriguing. These zones have very low GAD activity and low levels of endogenous GABA³; they accumulate ^3H -GABA *in vitro* in the presence of AOAA but not *in vivo*^{5,10}. This indicates that GABA-T is probably involved in GABA degradation in these zones. GABA-T activity may be present in the rod and cone cells but the uneven distribution of GABA-T activity and ^3H -GABA uptake indicates that there are specialised areas or structures involved. Fibrillar baskets originating from Müller's fibres at the external limiting membrane form around the proximal parts of the photoreceptor layer and it is possible that these baskets are the main sites of GABA-T activity and ^3H -GABA uptake *in vitro*⁶. The presence of a GABA-T mediated GABA inactivating mechanism in the photoreceptor layer would support

recent evidence that horizontal cells, which synapse with rod and cone cells, have a GABA-related inhibitory function in the retina^{3,13}. The uneven distribution of the GABA system within the retinal layers indicates that the system is compartmentalised between retinal cells. The evidence suggests that GABA synthesis, uptake and storage occurs in neuronal compartments, whilst uptake and degradation of GABA takes place to a large extent in a separate cellular compartment, probably glial. This is in agreement with other investigations into the GABA system in nervous tissue^{3,5,6,10,14,16}.

To obtain further information on the localisation of GABA-T in the inner plexiform and photoreceptor layers, we are currently examining the ultrastructural localisation of GABA-T activity in these areas.

We thank the Friedreich's Ataxia Group for financial assistance to J.C.H.

Remote nerve fibre bundle alterations in the retina as caused by argon laser photocoagulation

CONSIDERABLE information has been accumulated on the morphological characteristics of retinal lesions produced by laser sources¹⁻⁴. The argon laser is the most widely used energy source for clinical photocoagulation because of its optical and operational qualities.

Laser-induced retinal alterations characterised so far indicate that with increased energy, damaged areas include outer segment layers as well as the pigment epithelium, which is considered the primary site of absorption^{2,3}. Extremely low levels of coherent radiation also produce ultrastructural alterations in sensory retina without apparent change in pigment epithelium⁵. Most reports however have dealt primarily with the lesions or successful treatment⁶⁻⁸. Little information is available on possible secondary sites of injury which may not be spatially or temporally contiguous with the primary lesion. We describe here secondary alterations found considerable distances from the site of primary impact and not occurring immediately.

Single clinical level exposures were placed on retinal vessels as well as vessel-free areas in twelve rhesus monkey (*Macaca mulatta*) eyes. An argon laser, operating at 514.5

FIG. 1 Fundus photograph of 10-week-old exposures. Lesion 1 was placed at 300 mW, 1 s exposure and 150 μ m spot size. Lesion 2 was placed at 160 mW, 1 s exposure and 150 μ m spot size.

nm and TEM₀₀ mode, was used. The animals were observed for up to 1 year after exposure using direct ophthalmoscopy and fundus photography. Six eyes, from three animals, were enucleated and serial sections, stained with haematoxylin and eosin, were studied under light microscopy. Exposure levels, pulse durations and spot sizes used are given in Table 1.

Immediately after exposure, areas peripheral to the lesions exhibited no ophthalmoscopically visible changes. The colour and capillary network of the optic disk and surrounding tissue appeared normal. Within 5–10 d, however, a darker

area of tissue, of arcuate course and running through the lesions, extended both centrally toward the disk and peripherally away from the lesions, apparently following the distribution of nerve fibres and persisting for 1 yr after exposure (Fig. 1).

Examination of histo-pathological sections, taken 10 weeks after exposure, confirmed the presence of alterations corresponding to the darkened areas. Centrally toward the disk, a diminution of nerve fibres was evident. Other layers of the retina seemed to be unaltered (Fig. 3a). In the area of the lesions, outer segment, inner segment and outer nuclear layers of the retina as well as the pigment epithelium were affected, the extent of damage diminishing with distance from the centre of the impact site (Fig. 3b). Peripheral to the lesion sites, the thinning of the nerve fibre layer was accompanied by a diminution of ganglion cells (Fig. 3c). Again, as was the case central to the lesion all other retinal layers appeared unaltered. This effect is amply demonstrated in Fig. 2, corresponding to the fundus photograph (Fig. 1). Section A is central to both lesions, and compression of the nerve fibre layer, corresponding to the two darkened areas, is evident. Section B is through the site of lesion 1. Section C is peripheral to lesion 1 and central to lesion 2. The effect of lesion 1 shows compression of nerve fibres as well as thinning in the ganglion cell layer, while the effect of lesion 2 remains relatively unchanged from section A. Section D shows lesion 2 and the fovea. Section E is peripheral to both lesion sites and demonstrates the compression of nerve fibres and loss of ganglion cells in both cases. This effect seemed to be more pronounced in lesions placed on vessels than those placed on vessel-free areas.

The implications of this finding are numerous. Since damage to the nerve fibre bundle seems to be involved, the retina is being altered far from the primary site of damage. It has been reported that whenever there are visible nerve fibre defects in the arcuate or radial nerve fibres, corresponding defects are found in the visual field⁹. This type of damage implies both retrograde axonal, as

FIG. 2 Serial sections corresponding to Fig. 1. Section A is central to both lesions. Section B shows lesion 1 and thinning of nerve fibres corresponding to lesion 2. Section C depicts areas peripheral to lesion 1 and central to lesion 2. Section D shows lesion 2 and diminution of nerve fibres and ganglion cells as a result of lesion 1. Section E shows peripheral areas to both lesions 1 and 2.

TABLE 1 Power Levels, Spot Sizes, Pulse Durations and Retinal Locations used in obtaining Ophthalmoscopically Visible Nerve Fibre Damage

Power level (mW)	Spot size (μm)	Pulse duration (s)	Retinal location	Ophthalmoscopically visible Nerve fibre damage
125	100	1.00	Retinal vessel	1 of 1
			Vessel-free area	1 of 1
125	500	1.00	Retinal vessel	2 of 4
			Vessel-free area	0 of 1
160	150	1.00	Retinal vessel	1 of 1
300	150	1.00	Retinal vessel	1 of 1
250	50	0.50	Retinal vessel	0 of 1
350	50	0.50	Retinal vessel	1 of 1

well as Wallerian or ascending degeneration. One can generalise that the presence of these ophthalmoscopically visible dark streaks would indicate permanent involvement of optic axons and that the size of the field defect will equal or exceed the area predicted from the size of the retinal nerve fibre bundle damage.

Clinically, nerve fibre field defects have been associated with extremely high retinal energy densities and with repeated photocoagulation about the optic disk¹⁰. Seldom have they been assumed to be associated with initial treatment at moderate power levels. Presumably, the damage is thermal, where the increase in temperature is attributed to the radiation of heat from the underlying pigment epithelium, that is, incident light is absorbed by the pigment epithelium and converted into heat. After the initial photocoagulation, the retina is assumed to become thin so that the nerve fibre layer is in closer proximity to the retinal pigment epithelium causing a greater thermal gradient than in the initial treatment. Clinical power levels range from approximately 300 mW. (2 s pulse, 50–100 μm spot size) used to treat histoplasmosis choroiditis, to 100 mW. (0.1 s pulse, 50 μm spot size) used to treat retinal neovascularisation. Clearly our exposures lie within this range. Since rhesus monkey retina would tend to be more sensitive to laser radiation than that of humans (assuming the previously

discussed thermal considerations to be true), it is conceivable that this demonstrated effect is not as pronounced in the latter. This finding however does indicate that nerve fibre bundle damage is a distinct possibility at the presently used power levels. Much more work is required to establish the relationship of energy density and pulse duration to nerve fibre damage.

Temporal pattern of placental lactogen and progesterone secretion in sheep

HUMAN and monkey placental lactogens (PL) have been isolated and characterised biologically and chemically¹⁻³ and reports have appeared identifying a placental lactogen in rats⁴⁻⁶, mice⁷ and goats⁸. More recently rat serum PL concentrations have been determined quantitatively with a radioreceptor assay⁹. In the present study we have used the same assay with minor modifications to identify and measure plasma placental lactogen concentrations in sheep during pregnancy and have compared the secretory pattern of this new hormone with plasma concentrations of progesterone and pituitary prolactin.

We assayed plasma samples obtained at weekly intervals throughout pregnancy in three sheep. Blood samples were collected from animals housed in individual pens by needle puncture from the jugular vein into heparinised tubes. After centrifugation plasma samples were kept frozen at -20°C and some were stored for as long as 2 yr before assay. Lactogenic hormone in these samples was assayed by a radioreceptor assay which has been shown to be specific for lactogenic hormones. The assay uses membranes prepared from mammary glands⁹ of term pregnant rabbits. Plasma concentrations of pituitary prolactin were measured by a homologous, double antibody radioimmunoassay for ovine prolactin (OPRL) using ovine prolactin (NIH-P-S10, 26 IU mg^{-1}) as standard¹⁰. The progesterone concentration in these samples was determined by competitive protein binding assay¹¹.

We also examined in more detail the time course of changes in the concentrations of the three hormones that occur at parturition. Pregnant sheep were bled at intervals of 6 h from 96 h before to 60 h after parturition and the concentrations of all three hormones were determined.

Particulate membrane receptors were incubated with ¹²⁵I-OPRL and displaced by increasing concentrations of

Fig. 1 *a*, Displacement curves obtained when particulate membrane receptors were incubated with ^{125}I -OPRL (100,000 c.p.m.) in the presence of increasing concentrations of OPRL or dilutions of ovine placental extracts. The ordinate represents the amount of ^{125}I -OPRL bound to the receptors expressed as c.p.m. and the abscissa is the concentration of OPRL added to the assay tube. Values for tube blanks were subtracted from the total ^{125}I -OPRL bound to the membranes. The tube blanks were determined by counting the tubes which contained no membranes and were usually 3–4% of the total radioactivity added. The incubation was carried out at room temperature for 6 h. Membrane-bound and free hormone were separated by low speed centrifugation (750g) for 30 min. Foetal cotyledons were extracted for 4 h in 0.1 M NH_4NCO_3 (1 g per 20 ml) centrifuged and dilutions of the extract were assayed. *b*, Displacement curves obtained with serum or plasma samples. The assay procedures were identical to those described in the legend to (*a*), except that 25 μl of either normal human male serum (NHMS), hypophysectomised rat serum or normal sheep serum were added to each of the tubes containing the OPRL standards. When plasma rather than serum samples were assayed, it was necessary to add heparin to the diluting buffer to inhibit clot formation. The inset shows inhibition curves of dilutions of day 114 pregnant sheep plasma and OPRL in the presence of equivalent dilutions of NHMS. The 1:2 dilution was prepared by combining equal quantities of NHMS and OPRL, 2 $\mu\text{g ml}^{-1}$. *a*: ●, OPRL standard; ○, ovine placental extract. *b*: ●, OPRL standard (+ serum); ○, dilutions of day 114 pregnant sheep plasma; ▲, OPRL in presence of dilutions of NHMS.

unlabelled OPRL (Fig. 1). The curves obtained with dilutions of ovine placental extract were parallel to the OPRL inhibition curves (Fig. 1*a*). Despite concentrations of lactogen greater than 8 $\mu\text{g ml}^{-1}$ in the placental extract, the radioimmunoassay for pituitary prolactin failed to detect any lactogen in these extracts. The displacement curve for serum or plasma assays is shown in Fig. 1*b*. In this assay procedure the prolactin standard contained 25 μl of normal human male serum (NHMS). The inset shows the parallelism of dilutions of day 114 pregnant sheep plasma and OPRL in the presence of equivalent dilutions of NHMS.

Figure 2 shows the plasma concentrations of PL, prolactin and progesterone in samples from three ewes. Placental lactogen can usually be detected in plasma samples by day 60 of gestation and thereafter it increases as pregnancy advances, reaching peak concentrations of 1,000 to 2,000 ng ml^{-1} on days 95 to 114 of gestation. After the initial peak there is generally a decline in PL concentration followed by one or more peaks before parturition. These fluctuations, especially in ewe 187 (Fig. 2*c*) are reproducible and not due to assay variation, as similar overall patterns were observed on re-assay of the same plasma samples. The plasma concentrations of pituitary prolactin measured by radioimmunoassay remained below 50 ng ml^{-1} until a few days before parturition. So, except at term, the concentrations of PL measured by radioreceptor assay in plasma samples of pregnant sheep cannot be ascribed to the concentrations of prolactin of pituitary origin which is in the circulation.

Progesterone concentrations in two of the three animals very closely paralleled the temporal pattern of PL concentrations. In ewe 187 during the second half of pregnancy several peaks of PL were noted, only one of which exceeded 1,000 ng ml^{-1} . In spite of this, the progesterone concentrations in this animal were similar to those of the other two ewes.

The plasma concentrations of PL, prolactin, and progesterone at the time of parturition in three sheep are shown in Fig. 3. Placental lactogen concentrations slowly declined from approximately 1,000 ng ml^{-1} to 500–700 ng ml^{-1} by 12 h before parturition; they then decreased quite rapidly *post partum*. Plasma concentrations of pituitary prolactin began to rise about 36 h before parturition, reaching levels of 300–600 ng ml^{-1} approximately 3–6 h before parturition. At this time the PL concentrations measured by radioreceptor assay were almost entirely due to the cross reaction of pituitary prolactin in the receptor assay. During this time progesterone concentrations also fell rapidly together with PL concentration. In two of the three sheep the decrease in progesterone preceded that in PL by 6–12 h.

To estimate the relative halftime rate of disappearance of PL, the uterine vessels of two ewes were ligated on day 140 of pregnancy and plasma samples were collected. Assay of these samples by radioreceptor assay showed that PL disappeared from the circulation with a halftime of less than 20 min.

Fig. 2 Plasma concentrations of placental lactogen (PL) were measured by radioreceptor assay, plasma concentrations of pituitary prolactin (PRL) were measured by radioimmunoassay, and progesterone levels were determined by competitive protein binding assay during pregnancy in three sheep. The radioreceptor assay detects both PL and pituitary prolactin, however, except at term, the plasma concentration of the latter is trivial by comparison with PL levels. The radioimmunoassay for pituitary prolactin fails to detect placental lactogen. The arrow (↓) indicates the day of parturition. ●, Placental lactogen; ×, progesterone; ○, prolactin.

FIG. 3 Placental lactogen, prolactin and progesterone levels from 96 h before to 60 h after parturition in three sheep. Parturition occurred at some time between the intervals 6-0 and 0-6 h. ●, Placental lactogen; ×, progesterone; ○, prolactin.

Both the foetal and maternal cotyledons were extracted in 0.1 M NH_4HCO_3 . The concentration of PL in both extracts was 200 μg per wet weight of tissue which is similar to the concentration of PL human placental extracts². After fractionation of ovine placental extracts on Sephadex G-100, PL appeared in the same elution volume as ^{125}I -OPRL which had been added as a marker, suggesting that the molecular weights of PL and pituitary prolactin are very similar.

Several hormonal changes have been documented at the time of parturition in sheep. These include sequentially, an increase in blood cortisol in the foetus¹², followed by an increase in total unconjugated oestrogens¹³ and in the individual unconjugated oestrogens¹⁴ and a decrease in serum progesterone in maternal blood¹⁵ and, as we show here, a parallel decline in PL concentrations. The precise interrelationship and significance of all these hormonal changes is still obscure. Nevertheless, the general similarity of the temporal pattern of plasma concentrations of PL and progesterone is sufficiently intriguing to suggest that PL may stimulate progesterone production. With the purification of ovine PL in adequate amounts it should be possible to test this hypothesis directly. The fact remains that a new PL has been identified and quantified in plasma and placental extracts of pregnant sheep and this observation offers a new model to study the elusive role of placental lactogen.

We thank the National Institute of Arthritis and Metabolic Diseases for providing ovine prolactin. We thank Mrs Francine Bhavnani for secretarial help, Mrs Jean Parodo for preparing the figures and Miss Gloria Basug for technical

assistance. This research was supported by the Medical Research Council of Canada and a US Public Health Service Child Health and Human Development grant.

Cortical hypothermia is a sequela of electroconvulsive shock

THE impaired retention of a recently learned habit that is commonly observed in experimental animals after administration of electroconvulsive shock (ECS) is also observed after partial immersion for a few minutes in cold water¹⁻⁴. The physical differences between a hypothermal and an electrical amnesic agent do not preclude a common mode of action; indeed, we have confirmed that ECS results in hypothermia as well as amnesia.

Eight mature, partially pigmented rats were implanted surgically, under barbiturate anaesthesia, with two 2.5 mm stainless steel screw electrodes that were used to administer ECS and also to record the electrocorticogram (ECOG). In each rat electrodes were threaded through small bur holes in the calvarium to contact the dural membrane about 5 mm lateral to the midline, one electrode to the frontal cortex and one to the contralateral occipital cortex. A third electrode was screwed into the calvarium at the midline about 10 mm anterior to the bregma suture; this later served as an electrically indifferent pole for recording the ECOG. Each rat was also fitted with a small thermistor (United Systems model 430) that was lowered through a bur hole in the calvarium and then through an incision in the meninges to rest on parietal cortex near the vertex. Insulated conductive leads from each of the screw electrodes, and from the two leads of the thermistor, were dressed closely to the calvarium and then individually terminated at one of the five connector pins of a small socket anchored to the calvarium by dental cement. For a minimum of 7 d after surgery, the rats were housed continuously in individual cages in a vivarium where the ambient temperature was maintained between 22° and 26°C,

and relative humidity was between 50 and 70%. Purina Lab Chow was available *ad lib* in the home cage; so too was drinking water, until commencement of pretraining.

* Formal training trial of tenth day.

† Retention trial of twelfth day.

‡ Difference between number of Post-ECS and Pre-ECS entries.

Our measure of amnesia was a one-trial appetitive learning task developed by Tenen⁵ and independently confirmed^{6,7} as a mnemonic assay that controls for possible aversive sequelae of ECS. The task initially involved 10 successive days of pretraining during each of which, after 22 to 24 h without water, a rat was permitted to explore for 5 min the interior of an open-topped enclosure containing a nook in one wall. During all trials of pretraining, formal training and testing for retention, a set of flexible conductive leads was fastened to a rat's calvarium-pedestal; the shape of the nook accommodated the leads in such a way that an animal could enter and leave it without restriction. The formal training trial was conducted during the eleventh day, the only day in which a drinking tube that provided water was present in the nook. Fifteen seconds after each animal had begun to drink it was removed from the enclosure and was held while 40 mA (root-mean-square) of 60 Hz alternating sine-wave current was passed between the frontal and occipital screw electrodes for 0.5 s. Ten control rats, which shared a common history of origin, housing, surgery and pretraining, received sham-ECS treatment—no electrical current—but were otherwise handled in the same way. During the twelfth day, 22 to 24 h after ECS or sham ECS, each of the eighteen rats was returned to the enclosure and observed for 5 min, as under pretraining conditions, and its entries into the nook were counted.

The averaged number of entries of the ten unshocked rats of the sham-ECS group increased more than three-fold between the tenth day (6.3) and the twelfth day (21.5); on the twelfth day they behaved as if they expected to find water. In contrast, the eight shocked animals performed during the twelfth day about the same as they had during the tenth, respectively, averaging 10.2 and 7.5 entries; they seemed to remember little about the previous availability of water in the nook (Table 1). These findings were evaluated by subtracting the number of entries made by each rat during day 10 from the number it made during day 12; the *t* test for independent samples was then performed on the means of the difference scores, which were 2.62 and 15.20, respectively, for shocked and unshocked rats. The shocked group gave highly reliable evidence of poorer retention (*t* ratio = 5.13 at 16 degrees of freedom; $P < 0.001$).

The observations of primary importance to our study began just before the formal training trial of the eleventh day with a single 5 min recording of the baseline temperature

and then of the ECoG. Independent sets of flexible leads to a precision digital electronic thermometer (United Systems model 1502) and to a polygraph (Grass model 6-8-2) were attached sequentially to the calvarium-pedestal of each rat and then, after the thermal and the ECoG baselines had been recorded, were disconnected for attachment of the ECS leads. After the training trial and administration of ECS, alternate recordings of temperature and of the ECoG were made from time to time until the temperature of each rat was observed to increase to its baseline value. Cortical temperatures, which ranged from 36.4 to 38.0°C and averaged 37.2°C before ECS, decreased rapidly after the ECS treatment. The nadir of most of the shocked rats' temperatures occurred in about 15 min, ranged from 0.95° to 2.46°C below individual baselines, and persisted for about 30 min before a trend toward recovery was observed (Fig. 1). In all but one animal recovery to the baseline temperature occurred within 120 min. The one rat, however, exhibited a fluctuating hypothermia that persisted for nearly 10 h. Several days later, two of the eight experimental rats were selected randomly to provide additional baseline thermal data and were again subjected to the procedures of the eleventh day, except that they received sham ECS treatment. The brain temperatures of both animals during the 60 min recording session that followed were close to original baselines (Fig. 1).

When pre-ECS and post-ECS records of the ECoG and of the brain temperatures of individual animals were examined and compared, there was a marked covariation across time between thermal and electrocortical activity. The medium amplitude electrical activity of mixed, low-and-high frequencies that characterised the ECoG before ECS changed to the spiking and high-amplitude slow waves that characterise the electroencephalogram immediately after ECS⁸⁻¹⁰. A bout of isoelectric activity often followed the spiking and slow waves. Subsequently, until the cortical temperature began to increase, the ECoG was predominately one of slow wave, deltoid patterns. With initiation of thermal recovery there was a noticeable trend toward normalisation of the ECoG. Segments of the ECoG of a representative rat (Fig. 2) confirm to the eye the close correlation between electrical activity and temperature of the superficial cortex.

The major findings of our study are that: (i) a reversible cortical hypothermia is a consequence of an amnesia-inducing ECS; and (ii) the hypothermia is associated with an alteration of electrocortical activity. The degree of hypothermia

Fig. 1 The heavy line represents averaged decrements in degrees Celsius of cortical temperatures of eight rats after administration of a single electroconvulsive shock (ECS). The baseline of 0.0 °C is based on the averaged stabilised value of pre-ECS (basal) temperatures of the same animals. The dashed lines are individual thermal control data from two of the same rats as measured several days later after a sham-ECS treatment. The vertical lines extend one standard error above and below each mean.

FIG. 2 Representative segments of the electrocorticogram (ECoG) of a rat are shown in relation to its cortical temperature as recorded within a few seconds of each other and as sampled across time before and after a single electroconvulsive shock. The ECoG was recorded from the superficial frontal cortex and was referred to an indifferent electrode near the midline of the cerebrum.

that was exhibited by our rats after ECS seems to be less severe than that which has been reported as necessary to produce amnesia by partial immersion of the murine animal in cold water¹⁻⁴. For example, Beitel and Porter reported² that a reduction of core temperature to 2° C was necessary to achieve reliable amnesic effects in mice. In contrast, Vardaris *et al.* found⁴ that a reduction of the rat's core temperature to 21.5° C produced not only retrograde amnesia but also frank seizure-like activity in the ECoG. In neither study, however, was cerebral temperature measured. Indeed, the absence of published information on simultaneously recorded thermal data of brain and core from animals that have been subjected to, and confirmed by behaviour, for amnesic treatments renders moot the question of a possible lack of parity in the degree of cortical hypothermia. That there is a highly reliable if moderate cortical hypothermia in the rat after ECS is both warrantably assertable and provocative of a more general question: do other amnesic agents such as the cortical¹¹ and hippocampal¹² spreading depressions also result in cerebral hypothermia? An affirmative answer would suggest that cerebral hypothermia is a causal antecedent and not merely a correlate in the stream of events whereby memory of recent occurrences is impaired by ECS and other amnesic agents. If cerebral hypothermia *per se* is critical to the annihilation of a newly forming engram, artificial maintenance of normal temperatures of experimental subjects immediately after ECS—achieved, for example, by immersing them partially in warm water or by carefully dosing them with microwave energy¹³—should preserve the engram. A corollary of the argument, that a mild hyperthermia may facilitate formation and maintenance of the engram, has already gained some support in the literature^{13,14}.

Short term memory and the EEG

STUDIES of human short term memory and physiological state have produced what seem to be paradoxical results, as efficient performance has been associated with low states of activation. This effect was first demonstrated by Kleinsmith and Kaplan¹ who measured electrodermal response (EDA) to paired associates. As yet, no similar relationship has been demonstrated for EEG activation and memory. Previous studies have been concerned merely with the gross differentiation of task activity and rest and simply show greater activation during learning^{2,3}. No-one has reported a detailed study of changes during verbal learning or of their relationship to subsequent recall.

The EEG was monitored during the acquisition and immediate recall of 9-digit strings presented in the auditory mode. After an initial 2 min rest period, 32 subjects each underwent 24 trials, for which instruction was minimal. The EEG was recorded, stored and averaged, using low frequency analysis in the manner described in earlier studies⁴ to yield an average abundance value per serial position. Because of the limitations of low frequency analysis, inter-digit interval within a series was 3 s. Each trial lasted 45 s with an EEG sample for each of the 15 × 3 s intervals (9 × 3 s per series, plus 3 s warning, plus 15 s for recall and inter-trial rest). The results reported here are largely concerned with 11.5–12.5 Hz; a complete report will be presented later for theta, beta and the remaining alpha frequencies.

Our key results were as follows. Task errors in recall increased monotonically as a function of serial position (ANOVA; $P < 0.001$) with an improvement in performance

for the final serial position ($P < 0.05$). Such an error curve is typical for tasks of this nature. At the same time, EEG abundance during acquisition diminished with serial position, such that high error in subsequent recall was associated with decreasing abundance (increasing arousal) in acquisition (ANOVA; $P < 0.01$). The monotonicity of the decrease in abundance (as assessed by Kendall's S) was positively correlated with number of recall errors in each of the serial positions, the strongest effects holding for the earlier positions (Spearman's correlations by ranks (ρ); $P < 0.05/0.01$). Similarly, total abundance during acquisition was positively related to subsequent recall (Pearson product-moment correlations; $P < 0.01$).

When subjects were divided into high and low recall error groups, the high recall error subjects showed greatest decreasing abundance in both the later stages of acquisition and at recall (ANOVA; $P < 0.05$). Both high and low error groups yielded recall curves which were identical in shape and parallel. But subjects with high recall errors even showed lower abundance (7.5–13.5 Hz) during a pre-test resting period and mean dominant frequency⁵ at that time correlated positively with subsequent error rate (Spearman ρ ; $P < 0.05$).

A within-subjects analysis showed that both high recall error trials and low recall error trials began with a monotonic decrease in EEG abundance (increasing arousal); but good performance (low error) trials then departed from this trend and were associated with higher abundance (t test; $P < 0.02$). The first eight trials were associated both with high recall errors in the early serial positions (ANOVA; $P < 0.01$) and decreased abundance when compared with the final 16 trials (ANOVA; $P < 0.05$). Finally, for all subjects, EEG abundance during between-trial rest was greater than during acquisition and recall ($P < 0.01$).

So far as we are aware, this is the first study to plot the systematic changes which occur in the human CNS during acquisition of material to-be-recalled, and to relate such changes to subsequent recall.

These results were wholly consistent for every type of analysis (subjects before the task, subjects during the task, serial position, high and low recall error trials, trials over time) since poor performance was associated with increased EEG arousal, even to the extent of enabling prediction of recall error rate before the task proper. The results were also compatible with those of Kleinsmith and Kaplan¹ who showed that in paired-associate learning, items which were associated with high EDA arousal were less well recalled in the short term. The finding that the EEG is more activated during the trials compared with the inter-trial resting periods, corroborates earlier work^{2,3}. Within the range of this increased activation, however, superior performance is associated with relatively lower activation levels.

Thus, short term memory tasks are an exception when compared with other tasks demanding sustained attention, such as vigilance tasks, where efficiency is positively related to level of activation. Short term memory tasks of the digit span type, typically demand brief periods of undivided attention, after which the subject may relax and prepare himself for the next trial. Such conditions of testing may well require lower levels of initial arousal to ensure efficiency. It should be noted that in the present task, ample time was available for rehearsal and for the self-monitoring of success or failure in retention.

A provisional interpretation of our results is that subjects who were already more highly aroused were less suited to good performance than subjects with lower initial arousal level. In addition, knowledge of failure in retention may have augmented the trend to increased arousal which in its turn may have reduced further the quality of performance.

The immediate memory span test is long-established within the repertoire of psychological measurement, with many

decades of use in intelligence testing. Further experimentation using the present paradigm may lead to an increase of our understanding of the neurological substrates of intellectual functioning.

Visual attention affects brain blood flow

THE brain is extremely dependent on an uninterrupted supply of blood-borne nutrients because of its high metabolic rate. The effect of cerebral activity on the provision of blood to the brain, however, is not fully understood, particularly with respect to higher mental function. For human subjects, there is conflicting data concerning the possibility that intellectual effort increases the rate of flow of blood through the brain^{1,2}. We now report that cerebral blood flow may in part be regulated by the extent of mental activity. Our experimental animal was the chick, which has an anatomy such that minor changes in cerebral blood flow are readily detectable.

As the fibres of the optic tract are totally crossed over at the chiasm, each eye of the bird innervates only the contralateral optic lobe³. The cerebral hemispheres constitute the major associative areas of the chick and the innervation of each eye to these hemispheres, although indirect, is predominantly contralateral⁴. Furthermore, the absence of a major interhemispheric commissure, the corpus callosum, reduces interactions between the two symmetrical halves of the brain⁵. Consequently, the metabolic and vascular deficits caused by unilateral visual deprivation are largely confined to regions contralateral to the treated eye^{6,7}. Rapid and widespread changes in the rate of brain blood flow can be induced in chicks by occlusion of an eye by sewing the eyelids shut^{8,9}. However such studies cannot show whether reduced blood flow is due to reduced intensity of sensory input or to a decrease in behaviourally relevant information.

In our experiments two small cardboard blinkers were glued to the heads of 3-d-old chicks that had been fasted for the preceding day. The blinkers were positioned adjacent to each eye so that one eye could see only forward and the other only backward. Chicks were then placed in a smooth,

TABLE 1 Relative blood flow rates in the two sides of chick brain

Ln F/B

TABLE 2 Difference in blood flow ratios of equivalent regions of pecking and non-pecking chicks

	(ln F/B) pecking—(ln F/B) non-pecking	
Optic lobes	+ 0.072 ± 0.031	(<i>P</i> < 0.025)
Cerebral hemispheres	+ 0.050 ± 0.034	(<i>P</i> = 0.08)

F, B, P are explained in Table 1. Figures are means of differences ± s.e.

white, circular bowl (25 cm diameter, 13 cm high) containing grains of chick feed. Under these conditions all birds immediately began to feed with straight, forward pecks, using the forward-looking eye to locate the grain. After 10 min of feeding, the relative rate of blood flow through the left and right optic lobes and cerebral hemispheres was determined by intracardiac injection of ^{125}I -iodoantipyrine, which is freely diffusible through both aqueous and lipid media¹⁰. After 10 s, the chick was decapitated and the brain rapidly dissected, weighed and placed into scintillation vials for assay of total radioactivity⁸. Data are expressed as c.p.m. mg⁻¹ tissue (wet weight).

Results were calculated as the ratio of the specific radioactivity in the brain region contralateral to the forward-looking eye (F) relative to the corresponding value for the paired region contralateral to the backward-looking eye (B). To avoid skewing data, the natural logarithm of this ratio was determined for each chick (ln F/B). This value was significantly above zero for paired optic lobes and also cerebral hemispheres (Table 1). Thus, the regions innervated by the forward-looking eye had a significantly greater rate of blood flow than regions associated with the backward-looking eye. This occurred even though the intensity of light exposure was very similar for each eye.

The experiment was repeated on a second group of chicks under identical conditions, except that the bowl was devoid of grain. In this situation, chicks do not peck or attempt to peck. The animals were occasionally prodded gently to encourage them to keep their eyes open. Two birds that did not keep their eyes open were not used. When birds had been in the bowl for 10 min, regional cerebral flow was again determined as in the grain-pecking group (Table 1). In this case there was no significant difference in blood flow through regions innervated by the forward-looking eye relative to the backward-looking eye.

A statistical comparison was made between data derived from birds pecking at grain relative to birds not receiving grain (Table 2). The asymmetry of regional blood flow in the pecking chicks was also significantly greater than corresponding values for non-pecking chicks. Thus the production of a difference in blood flow in the two sides of the brain was demonstrable only when the chicks were given grain to peck. Because pecking grain is not a learned behaviour, some other behavioural factor, such as attention or interest must be involved.

Such visual attention is sufficient to increase the rate of blood flow by 7–9% in the directly innervated optic lobes, and in the secondarily innervated cerebral hemispheres. These regions account for more than 75% of the total brain weight in the chick.

Many reports suggest that increased rates of macromolecular synthesis by brain are associated with learning or with exposure to an enriched environment^{11–13}. As attention is a significant feature of all learning and enriched-environment studies, the phenomena described here may underlie some of the metabolic events related to these processes. Such an association could be explained by variations in the supply of metabolites to the brain as the result of changes in brain blood flow. Such vascular mechanisms could also mediate the known relation between the quality of sensory input and cerebral development.

Bioconvection patterns in swimming microorganism cultures as an example of Rayleigh-Taylor instability

RATHER definite spatial patterns are observed in cultures of swimming microorganisms which are heavier than water and which tend to propel themselves toward the upper surface in response to some external stimulus; for example, gravity, light and chemicals. These patterns are characterised by falling fingers containing the organisms and are maintained by return upward swimming of the organisms. The patterns have been termed 'bioconvection' patterns¹ and have been known since 1848²; they are found in bacterial, flagellate^{3,4}, plankton⁵ and ciliate⁶ cultures.

Wager² studied the patterns formed in cultures of the flagellate *Euglena viridis*, among others, and was able to show that the tendency for these organisms to swim against gravity (negative geotaxis) was necessary for the pattern formation with live organisms. When such organisms are dead and form a layer at the bottom of the culture, a similar pattern of falling fingers can be obtained provided a sealed airless chamber of such a culture is very carefully inverted². In this case, of course, the pattern is not maintained.

Bénard (thermal) instability has been considered as a mechanism for this pattern and has been disproved¹. Indeed, the patterns are observed even when a stabilising temperature gradient is imposed. Another mechanism which has been considered and invalidated⁷ is the turnover effect, which is common in sucrose gradient preparations for centrifugation.

Quantitative observations have been made recently⁷ of the development of bioconvection patterns in cultures of *Tetrahymena pyriformis*, a ciliated microorganism which ex-

FIG. 1 *a*, A strobe-illuminated photograph of bioconvective sedimentation fingers descending from precipitation nodes; view is from the side. This *Tetrahymena* culture is enclosed in a 0.15 cm thick perfusion chamber of diameter 2.1 cm. The multiple flash mode utilised here gives one an impression of the bioconvective motion. *b*, Precipitation nodes and cross connections in a *Tetrahymena* culture as viewed from above. All light areas are masses of cells reflecting light. White lines are connections, and junctions are precipitation nodes.

hibits negative geotaxis. The system of falling fingers which characterises the pattern follows a period of accumulation in the upper layer of the culture. This layer typically develops nodes or bulges downward with fairly regular separations. The bulges then grow into falling fingers which descend with a velocity approximately twice the normal swimming velocity of the ciliate. Eventually flow connections develop between the nodes in the upper layer, particularly at the higher organism concentrations. The resulting familiar bioconvection pattern is shown in Fig. 1*a* which is a side view and Fig. 1*b* which is a view from above.

When the patterns are fully established the upper layer typically has a thickness of the order of 1.5 mm. It can be deduced readily from ref. 7 that the concentration of organisms in this upper layer is so large that the average distance between organisms is small compared with the layer thickness. As we shall see, the distances between the organisms is also small compared with other possible lengths involved in the physical model with which we are concerned here.

In this physical model the upper layer is a homogeneous

fluid with an excess density determined by the presence of organisms which are heavier than the medium. Recent measurements⁷ lead to values of the density increments for the upper layer over the lower layer and, typically, density increments are found to range from $\Delta\rho = 1.21 \times 10^{-4}$ to $\Delta\rho = 1.1 \times 10^{-3} \text{ g cm}^{-3}$.

The physical view of the process which we adopt here is as follows. As the microorganisms swarm beneath the upper surface, they form a fairly well defined layer of thickness h , which has a density ρ' which exceeds the density ρ of the underlying culture by a small amount $\Delta\rho$. This upper layer is taken to be a homogeneous fluid even though it contains microorganisms. As has been indicated, the approximation of homogeneity is justified for the situation in which the organisms are numerous and uniformly distributed so that their separations are very small compared with the thickness of the layer and with other lengths involved in the physical model such as λ (the internodal distance defined below).

The physical situation is gravitationally unstable, of the sort which is familiar in fluid mechanics as Rayleigh-Taylor instability⁸. The unusual feature of the present conditions is that the gravity force is so small that viscosity becomes quite important. As is usual in a stability problem, the initial growth of a small disturbance is analysed, and for the present unstable case an initial disturbance grows like e^{nt} , where t is the time and n is a function of the wavelength of the disturbance. The exact treatment of this two-fluid problem, where the upper fluid has a small thickness, h and the lower fluid a large thickness has apparently not yet been published, but it is a relatively straightforward matter which, however, has considerable algebraic com-

FIG. 2 The ordinate gives n , the growth parameter of the initial interface wave disturbance which has amplitude increasing as e^{nt} . The maximum n is at $\lambda_m = \lambda_{\text{theor}}$ which occurs here at 0.65 and 0.525 cm. These theoretical curves are obtained for $\Delta\rho = 9.0 \times 10^{-4} \text{ gm cm}^{-3}$ with an upper layer depth of $h = 0.13 \text{ cm}$. The λ_m condition corresponding to this model is illustrated in Fig. 3.

TABLE 1 Measured and theoretical values for two *Tetrahymena* cultures

C_0 (cells cm^{-3})	3×10^4	2.71×10^5
h (cm)	0.15	0.13
C_l (cells cm^{-3})	0	5.6×10^5
C_u (cells cm^{-3})	7.1×10^4	1.4×10^6
$\Delta\rho$ (g cm^{-3})	1.21×10^{-4}	1.08×10^{-3}
λ_{meas} (cm)	~ 1.0	0.655
λ_{theor} (cm)(exact theory)	0.80	0.525
λ_{theor} (cm)(approximate theory)	1.1	0.65

The range of parameters shown is characteristic of *T. pyriformis* culture systems and although stated values of C_0 are exceeded in both directions no nodes appear at values below the smaller figure and cultures at values above the larger figure were not analysed. The symbols are defined in the text.

plications. Although the exact solution of this problem has been achieved⁹, the results are available in numerical form only. The results of the exact calculation for a layer thickness $h = 0.13$ cm and a density excess in the upper layer $\Delta\rho = 9.0 \times 10^{-4}$ g cm^{-3} is shown in Fig. 2. It can be shown⁹ that a simple approximation for the amplitude behaviour of a disturbance $a_k(t) = a_k(0)e^{nt}$ is given by

$$n^2 + 2\nu k^2 n - \sigma^2 = 0 \quad (1)$$

where

$$\sigma^2 = \frac{\rho' - \rho}{\rho' + \rho \coth kh} gk \quad (2)$$

Here $k = 2\pi/\lambda$ is the wave number, g is the acceleration of gravity and λ is the internodal wavelength. Figure 2 also shows n as a function of λ as determined from the approximate theory. Both the exact and the approximate theory show that n has a maximum at about the same value of λ . It is evident that there is a relatively small band of wavelengths about this maximum which leads in the growth of the fingers. The λ for which n is maximum, that is λ_m , should give the most frequently observed separation distance between the fingers. While the theory is limited to small amplitudes, it is clear that the wavelengths which lead initially will continue to lead.

For comparison with these theoretical ideas *T. pyriformis* was grown axenically and cultures were poured into dishes 4×5 cm in cross section. Fluid depth was maintained at 1.2 cm. Culture samples from the upper and lower layer were extracted by a device similar to that described previously⁷. Sample concentrations were determined with a Sedgwick-Rafter counting chamber and culture concentrations with a Coulter counter. Swarm layer thickness, h , was determined from photographs. The density increment was found from

$$\Delta\rho = (C_u - C_l)(m_T - V_T\rho_M),$$

FIG. 3 Rayleigh-Taylor instability parameters measured for one culture of *T. pyriformis*. The $\lambda_m = 0.655$ is an average nearest internodal distance obtained from nodes at least 1 cm from the chamber wall.

where C_u and C_l are upper layer and lower layer medium cell concentrations respectively, m_T and V_T are the mass and volume respectively of *T. pyriformis*, and ρ_M is the culture fluid density. Parameters for a sample culture are presented in Fig. 3.

Table 1 summarises two sets of measurements near the extremes of the observed culture concentration range. The table also gives a comparison of the observed internodal distance with the values predicted by the present theory.

The agreement between the theoretical and observed maximum values is good. We conclude that Rayleigh-Taylor instability is the mechanism for the observed bioconvection in *T. pyriformis* cultures and may also explain sedimentation patterns in other microorganism swarms insofar as they are not disturbed by surface wind or by thermal gradients.

We thank Christopher Whipple for the calculations which led to Fig. 2, and the National Science Foundation for a grant.

Decrease of polysomes in *Tetrahymena* after synchronisation shocks

THE rate of protein synthesis in eukaryotic cells can change rapidly as a result of translational control such as the inhibition of protein synthesis during mitosis¹ or starvation²⁻⁴. Under these conditions a reversible inhibition of the initiation step of protein synthesis decreases the rate at which ribosomes become attached to messenger RNA. The continuing runoff of ribosomes from messenger during protein chain elongation and termination depletes the percentage of the total ribosomes which are in the form of polysomes and are synthesising protein.

Tetrahymena is a convenient cell in which translational control can be studied by measuring the percentage of polysomes under a variety of conditions. Of particular interest are the effects of temperature shifts which synchronise cell division in *Tetrahymena* cultures^{5,6} and which cause rapid and reversible inhibition of the initiation step in mammalian cells⁷⁻¹⁰. This report shows that temperature shifts, hypoxia and deprivation of nutrients all cause rapid, reversible decreases in the percentage of polysomes in *Tetrahymena* due to an inhibition of initiation. In previous reports decreases in the percentage of polysomes in this organism were noted only after long periods of cold shock¹¹ or starvation¹², and fractionation techniques were used which permitted considerable degradation of the polysomes.

Tetrahymena pyriformis (strain T) growing at 28°C in 2% proteose peptone-0.2% yeast extract was harvested in exponential phase and lysed with detergent in the presence of 100 μg heparin ml^{-1} . Centrifugation of the lysates on sucrose density gradients showed that about 75% of the

Fig. 1 Sucrose gradient centrifugation of *Tetrahymena* polysomes. Cells were collected by chilling the cultures ($0.5 - 1 \times 10^5$ cells ml^{-1}) and centrifuging at 0°C , washed once with 1 mM MgCl_2 - 10 mM KCl -10mM tris-HCl (pH 7.4) - 40 mM NaCl , suspended in 5 mM MgCl_2 - 5 mM mercaptoethanol - 20 mM Tris-HCl (pH 7.4) - 100 mM KCl - 250 mM sucrose containing 100 μg heparin ml^{-1} , and lysed by adding Nonidet-P40 to 0.2% and sodium deoxycholate to 1.0%. The lysate was centrifuged (12,000g, 15 min) and portions of the supernatant (equivalent to approximately 3×10^5 cells) were layered over non-isokinetic sucrose gradients¹³ (8.5 ml 10% to 50% sucrose over 0.5 ml 50% sucrose) containing 5 mM MgCl_2 - 10 mM Tris-HCl (pH 7.4) - 100 mM KCl . After centrifugation at 4°C (75 min, 30,000 r.p.m.) the distribution of ribosomes and polysomes was determined by pumping the gradient from the bottom of the tube through an LKB 4 mm square section flow cell. The extinction at 260 nm was continuously recorded with a Gilford model 2000 recording spectrophotometer. Treatment with pancreatic ribonuclease (25 μg ml^{-1} , 10 min at 25°) was carried out just before layering on the gradient. —, control; ---, RNase.

ribosomes were in the form of polysomes which sedimented more rapidly than the free (80S) ribosomes, but which were degraded to 80S structures by added pancreatic ribonuclease (Fig. 1).

The effects of inhibitors of translation demonstrated that the polysomes in the cell were steady-state structures resulting from a balance between the rate of ribosome attachment (initiation) and the rate of ribosome runoff. Cells incubated in growth medium containing ^{14}C -leucine (0.5 μCi ml^{-1} , 50 μCi μmol^{-1}) incorporated radioactivity into hot trichloroacetic acid-precipitable material at a linear rate for 60 min. This incorporation was inhibited 70% by 50 μM 2-(4-methyl-2,6-dinitroanilino)-N-methyl propionamide (MDMP), an inhibitor of initiation^{14,15}, and 50% by cycloheximide (0.5 μg ml^{-1}) which inhibits chain elongation. Figure 2 shows that 50 μM MDMP decreased the proportion of polysomes to 30% in 10 min. This effect was reversed by low concentrations of cycloheximide which, by partially inhibiting chain elongation, slow down the transit of ribosomes over the messenger, so preventing the depletion of the polysomes by the initiation inhibitor (see for example ref. 1). In the same way cycloheximide added to control cells increased the percentage of polysomes to 85-90%.

In contrast with these rapid effects other experiments (results not shown) demonstrated that 50 μg actinomycin ml^{-1} (which inhibited ^{14}C -uracil incorporation into the RNA

of intact cells by 95%) affected the percentage of polysomes much more gradually. Thus the percentage of polysomes fell from 76% to 70% after 30 min, and to 40% after 90 min, while ^{14}C -leucine incorporation was approximately 50% inhibited after 90 min. This suggests that rapid changes of the percentage of polysomes are unlikely to depend on changes in the rate of RNA synthesis.

When cells in growth medium were subjected to heat shock by raising the temperature to 34°C for 10 min the proportion of polysomes decreased to 45% (Fig. 3a and Table 1) and ^{14}C -leucine incorporation by the intact cells was 33% inhibited. When the cells were returned to 28°C , recovery was essentially complete and was unaffected by the presence of actinomycin (50 μg ml^{-1}). The decreased proportion of polysomes at 34°C reflected an altered balance between attachment and runoff of ribosomes, and cycloheximide (0.5 μg ml^{-1}) restored the percentage of polysomes to approximately the normal level presumably by slowing down the runoff of ribosomes (Table 1). A decrease in the number of polysomes could result from a decreased rate of ribosome attachment to mRNA (initiation) or from an increased transit rate of ribosomes over mRNA. Since protein synthesis was inhibited at 34°C the decreased percentage of polysomes probably reflected an inhibition of initiation. After 30 min at 34°C recovery at 28°C was incomplete (Table 1) which suggests a loss of messenger during the longer period at 34°C . It has been shown that at this temperature RNA in *Tetrahymena* breaks down more rapidly¹⁶ and stability of messenger (measured subsequently at 28°C as the capacity for protein synthesis in the presence of actinomycin) is decreased¹⁷.

Shifting the cells to 10°C inhibited protein synthesis by 80% and affected the polysomes in the same way as heat shock (Table 1 and Fig. 3b). Thus the percentage of polysomes was approximately 40% after 15 min or 60 min

Fig. 2 Effect of MDMP (....), cycloheximide (—) and MDMP plus cycloheximide (---) on *Tetrahymena* (polysomes). Cell cultures in growth medium were incubated at 28°C for 10 min with added cycloheximide (0.5 μg ml^{-1}) or MDMP (50 μM). Samples of cell lysate (equivalent to approximately 5×10^5 cells) were centrifuged as in Fig. 1. Values for percentages of polysomes determined from the absorbancy tracing at 260 nm are cycloheximide 85%, MDMP 30%, MDMP + cycloheximide 61%. The values for controls without inhibitor were 72-76%.

FIG. 3 Effect of temperature shifts on *Tetrahymena* polysomes. Cultures in growth medium were incubated as follows. *a*, (Heat shock): at 28°C, 10 min at 34°C, or 10 min at 34°C followed by recovery for 10 min at 28°C. *b*, (Cold shock): at 28°C, 15 min at 10°C, or 15 min at 10°C in the presence of cycloheximide ($0.5 \mu\text{g ml}^{-1}$) (— — —).

of cold shock and this decrease was prevented by cycloheximide. Recovery at 28°C was rapid and virtually complete even after 60 min at 10°C. This is in agreement with the finding that messenger is stable at low temperatures¹⁷.

Hypoxia has been used to synchronise *Tetrahymena*¹⁸ and may have an effect analogous to starvation of energy substrates⁴ which, like amino acid starvation^{3,4}, inhibits initiation of protein synthesis in mammalian cells. After 30 min of hypoxia in growth medium or 10 min of starvation in a saline medium the polysomes were decreased to about 40% (Table 1). In both cases cycloheximide prevented the depletion of polysomes and recovery was rapid though incomplete when normal conditions were restored. If the unlikely possibility that hypoxia or starvation increased the rate of ribosome transit on mRNA is excluded, then the decrease in the number of polysomes under these conditions must have resulted from a reversible inhibition of the initiation step.

Therefore, as in mammalian cells, temperature shifts and starvation seem to decrease the percentage of polysomes in

TABLE 1 Percentage of Polysomes in *Tetrahymena* under Various Conditions

Incubation conditions	% of polysomes		
	Incubation without cycloheximide	Incubation with cycloheximide	Incubation without cycloheximide, then 10 min at 28°C in growth medium
34°C for 10 min	45	78	74*
34°C for 30 min	46	—	62
10°C for 15 min	41	71	—
10°C for 60 min	40	—	71*
Hypoxia, 30 min	42	73	64
Starved, 10 min	42	60	64†

The percentage of polysomes was determined as in Fig. 2 after temperature shift (Fig. 3), hypoxia (cultures in growth medium at 28°C gassed with nitrogen) or starvation (cells suspended in 1 mM MgSO_4 — 5 mM potassium phosphate (pH 7.0) — 45 mM NaCl at 28°C). These conditions were modified as shown by including cycloheximide ($0.5 \mu\text{g ml}^{-1}$) or by permitting recovery by subsequent incubation for 10 min in growth medium at 28°C. Values are averages of two or more results (which agreed within approximately 5%). In control cells (growth medium at 28°C) the proportion of polysomes was 73–77%.

* Results after recovery in the presence of actinomycin ($50 \mu\text{g ml}^{-1}$) were essentially the same.

† Similar results were obtained when an equal volume of double-strength growth medium was added or when the cells were centrifuged at 0°C and resuspended in growth medium at 28°C.

Tetrahymena by inhibiting initiation. Messenger not engaged in polysome formation may as in *Escherichia coli*^{19,20} be more susceptible to degradation, especially at higher temperatures. In this way inhibition of initiation during relatively short periods at 34°C or longer periods at 10°C could contribute to that depletion of messenger for proteins related to cell division which is the probable basis of synchronisation⁵.

We are grateful to Dr R. V. Quincey for helpful discussion, to Dr R. Baxter for a supply of MDMP and to the Medical Research Council for a Research Grant.

New genetic and physicochemical data on structure of dinoflagellate chromosomes

THE majority of free-living dinoflagellates differ from other eukaryotes in possessing high chromosome numbers¹, large amounts of DNA² per cell, uniform chromosome size and in their apparent lack of histone proteins³. One of their most interesting properties which they share along with the euglenids⁴ is the condensed state of their chromosomes throughout the cell cycle⁵.

These chromosome properties immediately suggest three simple models for nuclear DNA organisation: (1) a normal pattern of alternation of haploid and diploid generations with each haploid chromosome non-identical; (2) polyploidy, having three or more sets of homologous chromosomes and (3) polyteny, a multistranded condition of chromosomes found for example in *Drosophila* salivary glands. Haapala and Soyer⁶ have recently proposed a diploid-polyteny model for the organisation of the dinoflagellate nucleus. On the basis of our work on *Cryptocodinium cohnii* (Seligo) Chatton in Grassé, 1952 (GC strain, Indiana University Culture Collection No. 1649), and other dinoflagellates we take issue with this model for the following reasons. Haapala and Soyer⁶ assumed dinoflagellates to be diploid. To date all except possibly *Noctiluca*⁷ have been cytologically determined to be haploid⁸⁻¹². Our chemical mutagenesis studies using N-methyl-N'-nitro-N-nitrosoguanidine have demonstrated that nutritional and carotenoid deficient mutants can be obtained at a frequency similar to bacteria¹³. (Chemical mutagenesis of *C. cohnii* was carried out by the method of Adelberg *et al.*¹³, with the following modifications: temperature = 25° C, final concentration of nitrosoguanidine = 20 µg ml⁻¹, carried out in M buffer (342 mM NaCl, 28 mM MgSO₄, 2 mM CaCl₂, 9 mM KCl, 8 mM 4-morpholine-ethane sulphonic acid, final pH = 6.0). Treatment time = 6 min. Under these conditions, the mutation frequency for purine and pyrimidine requiring strains was in the range of 0.17-0.83% of survivors and for carotenoid deficient strains in the range of 0.2-0.29% of survivors. Adelberg *et al.*¹³ obtained valine resistance in *E. coli* K12 at a maximum frequency of 0.20% survivors.) Only a haploid nuclear condition would be consistent with the frequency of mutations obtained. To find a viable mutant of diploid organism one would have to mutate the same gene on both homologous chromosomes without causing additional lethal mutations elsewhere in the genome. So, the frequency of obtaining conditionally lethal mutants is very small in a diploid organism. For the above reasons mutational data also rule out simple polyteny and polyploidy, where every single gene on every chromosome is polytenised or where every chromosome is present in two or more copies. Our DNA renaturation kinetic studies on *C. cohnii* also rule out polyteny and extreme polyploidy, where every chromosome is exactly the same. From DNA measurements on exponentially growing cells we find 6.9 µg per 10⁶ cells by two spectrofluorometric methods: ethidium bromide¹⁴, and diaminobenzoic acid^{15,16}, which agree with the reported value of 6.9 µg per 10⁶ cells obtained with the diphenylamine method¹⁷. Using the acetocarmine technique¹⁸ we have obtained counts of 107 and

110 chromosomes for *C. cohnii* in close agreement to the reported¹⁹ value of 99. Assuming all of the chromosomes have roughly the same amount of DNA, we calculate 4.2×10^{10} daltons per chromosome. If extreme polyploidy were the case, then the slowest renaturing component of *C. cohnii* DNA would renature at a rate no more than twenty times slower than *Escherichia coli* strain C600 DNA which has about 2.2×10^9 daltons per chromosome¹⁴. Figure 1 presents renaturation kinetic measurements of *C. cohnii* and *E. coli* DNA. Although it is obvious that there is a component comprising roughly 60% of the dinoflagellate DNA which renatures at a rate comparable to *E. coli* the remaining 40% is not renatured at C_0t value sixty times greater than the $C_0t_{1/2}$ of

FIG. 1 The kinetics of re-association of the DNA from the dinoflagellate *C. cohnii* compared with that of the bacterium *E. coli* C600. The DNA of both organisms was isolated by the method of Marmur²⁰ and tested for purity by CsCl equilibrium density ultracentrifugation and optical melting analysis. DNA was sheared by sonication to fragments of 500 ± 50 nucleotide pairs (as measured by sedimentation rate in the Spinco Model E ultracentrifuge). Samples of DNA in 120 mM phosphate buffer were denatured by heating to 100° C for 5 min and then allowed to renature for various times at $60 \pm 1^\circ$ C. The samples were then passed over a hydroxyapatite column at 64° C to separate quantitatively single and double stranded DNA. DNA concentrations were: \times , 190 µg ml⁻¹ *E. coli* DNA; \square , 500 µg ml⁻¹ *C. cohnii* DNA; \circ , 100 µg ml⁻¹ *C. cohnii* DNA.

E. coli DNA. If *C. cohnii* were 500 times polytene as proposed by Haapala and Soyer⁶, the slowest component of the DNA should renature no more than four times more slowly than *E. coli* DNA; that is, $C_0t_{1/2} \leq 40$. Our measurements indicate the $C_0t_{1/2}$ of the 60% component of the dinoflagellate is about 1, and its kinetic complexity is estimated to be 2.5×10^8 daltons ($1/10 \times$ kinetic complexity of *E. coli* DNA). The amount of DNA comprising this component is 2.4×10^{12} daltons per nucleus, thus the sequences are repeated about 10,000 times. Repeated sequences of such high complexity are unusual, and might be important in establishing the evolutionary history of dinoflagellates. The remaining 40% of the DNA is not appreciably renatured at C_0t 600. Since the C_0t plot representation of the renaturation of the 40% component must have a finite slope no steeper than -20 (% unrenatured/ $\log C_0t$) as predicted from theory, the $C_0t_{1/2}$ of this slowly-renaturing component can be no less than 3000; and thus the DNA of this component can be repeated no more than ten times per cell. Thus our renaturation kinetics and chemical mutagenesis studies do not support the conclusions of Haapala and Soyer⁶ of a diploid-polytene nature of the dinoflagellate nucleus. Their suggestion of multiple circular DNA molecules composing a dinoflagellate chromosome is

however, very intriguing. Whether each chromosome contains one or several pieces of DNA may be tested using the viscoelastic technique^{14,21}.

Protein densities from X-ray crystallographic coordinates

DENSITIES of the interiors of nine protein molecules were calculated using atomic coordinates obtained by X-ray crystallography. The resulting values, obtained for spherical regions of the molecules surrounding their centres of mass, are 10–25% below the apparent densities of the same molecules in solution. These regions include 20–50% of the total molecular mass. The densities calculated were 1.09–1.25 g cm⁻³ whereas the observed apparent solution densities of these proteins are 1.33–1.42 g cm⁻³.

Calculations were performed as follows. All atoms in each molecule were identified and assigned appropriate masses, including hydrogens, which are not generally located by protein X-ray crystallography (thus, all α -carbons except proline were given mass 13; all peptide nitrogens except proline, 15; the alanine β -carbon, 15; the lysine epsilon amino nitrogen, 17, and so on). The molecular centre of mass was located and its distance from each atom was determined. The masses of all atoms within shells 0–2 Å, 2–4 Å, 4–6 Å, and so on, from the centre of mass were added, and the sum

divided by the shell volume to give a 'shell density.' 'Mean densities' for spheres of radii 2 Å, 4 Å, 6 Å, and so on, were also calculated by dividing the total mass enclosed within each sphere by the sphere volume.

Results for five proteins are shown in Figs 1 and 2. The innermost shell densities vary widely due to their few atoms. Farther out in the molecule shell and mean densities of 1.02–1.27 and 1.14–1.22 g cm⁻³, respectively, are found. When shells become large enough to include solvent molecules (which were not included in the calculations), the shell density declines. The outer radius of the shell beyond which this decline begins is called R_{max} ; all points within R_{max} are presumed to lie entirely within the molecular cavity. The

FIG. 1 Dependence of shell densities on shell radius. ○, Carboxypeptidase; △, subtilisin; □, chymotrypsin; ●, myoglobin; ■, lysozyme.

mean density of the sphere of radius R_{max} , calculated as just described, is denoted by ρ_{calc} , and the observed apparent density of the protein, as obtained from solution density measurements, is ρ_{obs} . (In two instances ρ_{obs} will be the value calculated by the Cohn-Edsall method, which generally agrees well with solution density values¹.)

Table 1 gives R_{max} , ρ_{calc} and ρ_{obs} for nine proteins. Column 6 shows that ρ_{calc} is 0.10–0.36 g cm⁻³ below the corresponding ρ_{obs} (the mean difference is 0.21). Column 3 gives the fraction of the total molecular mass within the sphere of radius R_{max} . The abnormally low densities refer to only the central 20–50% of the molecule.

Three explanations for this discrepancy are conceivable. (The possibility that the apparent protein density in the crystal differs to this extent from the density in solution seems to be excluded by the measurements of Low and Richards^{2,3} and of McMeekin, Groves and Hipp⁴.)

(a) The protein has the density ρ_{calc} throughout, but may be surrounded by an abnormally dense water jacket. To estimate the density in this jacket an equivalent radius, R_{eq} , was calculated for two of the proteins from the known

† An assumed value, included to show, by comparison with the alternate value, the sensitivity of columns (10)–(12) to the value of ρ_{obs} .

‡ Same value is obtained when ρ is calculated from the amino acid composition by the Cohn-Edsall method¹.

§ Value calculated from amino acid composition by the Cohn-Edsall method¹.

TABLE 2 Density of water jacket required to raise the calculated densities, ρ_{calc} , to the observed apparent solution densities, ρ_{obs}

Jacket thickness (Å)	3.0	6.0	9.0	15.0
ρ_{jacket} { Myoglobin g cm ⁻³ { Carboxypeptidase	{ 1.624 1.547	{ 1.467 1.426	{ 1.418 1.387	{ 1.381 1.357

total molecular mass and ρ_{calc} . ($R_{\text{eq}} = (3M/4\pi N_0 \rho_{\text{calc}})^{1/3} = 18.08$ Å for myoglobin, with $M = 17756$, $\rho_{\text{calc}} = 1.19$; $R_{\text{eq}} = 22.28$ Å for carboxypeptidase, with $M = 34337$, $\rho_{\text{calc}} = 1.23$.) The required jacket density is then $\rho_{\text{jacket}} = [\rho_{\text{obs}}(R_{\text{eq}} + t)^3 - \rho_{\text{calc}}R_{\text{eq}}^3]/[(R_{\text{eq}} + t)^3 - R_{\text{eq}}^3]$, t being the jacket thickness. The value $t = 3.0$ Å is equivalent to a jacket about one water molecule thick. Table 2 shows that water densities of 1.35–1.60 are required to bring ρ_{calc} to the observed value if the jacket is 1–5 water molecules thick. (ρ_{obs} was given values 1.35 for myoglobin and 1.33 for carboxypeptidase.)

Electrostriction by charged groups could account for only a portion of such a density increase. Columns 7, 8 and 9 of Table 1 give the numbers of positively and negatively charged side chains on each protein molecule and the apparent density increase, $\Delta\rho_{\text{elect}}$, resulting from a 10 cm³ mol⁻¹ electrostrictive contraction per charged group. Evidently $\Delta\rho_{\text{elect}}$ is 0.025–0.05 whereas the discrepancy, $\rho_{\text{obs}} - \rho_{\text{calc}}$, is 3.4–12 times greater than this.

A structureless water jacket with $\rho = 1.3$ –1.6 might be detectable as a halo of high electron density on X-ray Fourier maps; we understand that this is not observed.

(b) The outer portion of the molecule may have a higher density than the central region. This difference would be expected if the interior of the molecule contains mostly hydrophobic groups and if polar groups tend to be found near the molecular surface. (Solid straight chain paraffins and benzene have densities of about 1.0. Most proteins, however, have peptide groups buried in their interiors as β -sheets and α -helices. Cohn and Edsall give 20 cm³ as

the mole volume of the $-\text{CO}-\text{NH}-$ group, equivalent to 2.15 g cm⁻³. Thus the interior density should be somewhat above 1.0.) Apparent densities, ρ_{outer} , of the outer regions were calculated by dividing the difference between the total molecular weight and the mass enclosed within R_{max} by the difference between the volume bounded by R_{max} and the total molecular volume, as calculated from the molecular weight and the observed partial specific volume in solution. These are shown in Table 1, column 10. Values range from 1.43 to 1.63; all but two are above 1.50. These densities are large compared with the known densities of solid peptides. Among the solid simple peptides only diglycine (1.71) and glycyl alanine (1.55) have such high densities. Solid polyglycine has a density of 1.51, but other solid synthetic polypeptides are much less dense: polyalanine, 1.28; poly γ -methyl L-glutamate, 1.32; poly γ -benzyl DL-glutamate, 1.28. Silk fibroin, a rather polar extended protein molecule, has a density of 1.36. Densities of about 1.50–1.55 for the molecules' outer regions are thus somewhat above what might be expected from the known densities of peptides, polypeptides, and dry proteins generally.

The polar and non-polar character of regions inside and outside R_{max} are compared for four proteins in Table 3, which shows the numbers of different types of atoms with distances from the centre of mass less than and greater than R_{max} . In these proteins, hydrophobic atoms are slightly more common in the interior than in the exterior. None of the $\phi_</\phi_>$ values can, however, be considered to indicate a tendency for the typical protein molecule interior to be markedly more hydrophobic than the exterior—a fact already evident from the work of Lee and Richards⁵. It is thus difficult to attribute the density discrepancy to a markedly different composition of the inner and outer portions of these protein molecules.

(c) Many water molecules may exist throughout the interiors of protein molecules. Column 12 of Table 1 shows the number of internal water molecules required to account for the difference between ρ_{calc} and ρ_{obs} . Numbers of the

TABLE 3 Numbers of different types of atoms present inside and outside of a sphere of radius R_{max} centred on the centre of mass

Protein	$R < R_{\text{max}}$				$R > R_{\text{max}}$				$\phi_<$	$\phi_>$	$\phi_</\phi_>$
	C_α	C_{hyd}	Polar atoms	Haem	C_α	C_{hyd}	Polar atoms	Haem			
Lysozyme	49	144	178	0	79	211	339	0	0.809	0.622	1.30
Myoglobin	48	173	148	34	108	334	446	10	1.399	0.771	1.81
Carboxypeptidase	162	538	583	0	145	409	599	0	0.923	0.682	1.35
Subtilisin	131	295	439	0	144	359	575	0	0.672	0.624	1.08

'Polar atoms' include oxygen, nitrogen and carbonyl carbons, ' C_α ' are the main chain α -carbon atoms, and ' C_{hyd} ' are all other carbon atoms—considered to be hydrophobic. $\phi_<$ and $\phi_>$ are the ratios of the numbers of ' C_{hyd} ' + 'Haem' atoms to 'polar atoms' for $R < R_{\text{max}}$ and $R > R_{\text{max}}$, respectively.

Fig. 2 Dependence of mean density of spherical regions on sphere radius. \circ , carboxypeptidase; Δ , subtilisin; \blacksquare , chymotrypsin; \bullet , myoglobin; \square , lysozyme.

order of 100–300 are indicated. Birktoft and Blow⁶ have detected approximately 16 localised water molecules within the chymotrypsin molecule. A much larger number than this is believed unlikely for proteins in general.

The second explanation (low density centre, higher density exterior) seems to be the most plausible, but contributions from all three factors are conceivable.

Atomic coordinates used in this study were supplied by the following: carboxypeptidase, W. Lipscomb; chymotrypsin, D. M. Blow; chymotrypsinogen, H. T. Wright; subtilisin, J. Kraut; lamprey haemoglobin, W. Love; lysozyme, D. Phillips; myoglobin, J. C. Kendrew; ribonuclease, F. M. Richards; staphylococcal nuclease, F. A. Cotton. The Princeton University Computer Centre facilities were used in making the calculations. The work was supported by a US National Science Foundation grant.

Control of Zea root elongation by light and the action of 3,5-diiodo-4-hydroxybenzoic acid

THE inhibitory effect of white light on the elongation of the primary roots of wheat and rice seedlings has been reported^{1–4}. It would seem that light affects the ability of the cells to increase in length and also reduces the meristematic activity of the root^{1,4}; the latter process may be dependent on the wavelength of the incident radiation⁴. Other studies here have shown that the chemical 3,5-diiodo-4-hydroxybenzoic acid (DIHB) can completely remove the inhibitory effect of light on the roots of rice and cress seedlings. This was achieved mainly by enhancement of cell elongation and not by stimulation of cell multiplication^{5,6}.

Following the discovery, in these laboratories, of the plant growth inhibitor xanthoxin (formed as a photo-oxidation product of certain xanthophyll epoxides⁷ known to occur in cereal roots^{8,9}) we decided to assess the possible role of the new inhibitor in the control of root elongation by light in relation to the action of DIHB.

Initial investigations were carried out to establish whether an exogenous application of xanthoxin affected the elongation of the primary roots of *Triticum* seedlings. Eclipse wheat seeds germinated for 20 h at 25°C in darkness to give a radicle length of 1 mm, were placed on Whatman No. 1 filter paper (5.5 cm diameter) in glass Petri dishes containing 2 ml of the appropriate test solution. Root length was measured after a 20 h incubation period at 25°C in white light (Mazda daylight fluorescent tube) or total darkness. Light

Fig. 1 Effect of 10 μ M xanthoxin and 0.1 mM DIHB solutions on the elongation of the primary roots of *Triticum* seedlings. Shaded areas are the mean of three independent experiments in which each treatment consisted of eight replicate seedlings. A, Control; B, DIHB; C, xanthoxin; D, xanthoxin and DIHB. a, light; b, dark.

FIG. 2 Effect of root decapitation and 0.1 mM DIHB solution on the elongation of the roots of *Zea* seedlings exposed to white light or darkness. Shaded areas are the mean of four independent experiments in which each treatment consisted of eight replicate seedlings. a, light; b, dark.

exposure was found to induce a 21% reduction in the length of the wheat seedling roots. Application of a 10 μ M aqueous solution of xanthoxin resulted in an 83% reduction in elongation in the dark and a 72% reduction in the light compared with the water controls, (Fig. 1). Treatment with 0.1 mM DIHB solution gave a 56% increase in root elongation in the light and a 25% increase in darkness. A solution of 10 μ M xanthoxin, together with 0.1 mM DIHB, however, caused a 59% reduction of root elongation in the dark and only a 27% reduction in the light. In other words, DIHB seems to antagonise the inhibitory effect of xanthoxin on root elongation and this antagonism is more pronounced in the light than in the dark. An interaction of this type would be expected if xanthoxin was, in fact, involved in the endogenous inhibition of root elongation.

Further investigation⁹ revealed that xanthoxin could not be isolated from the roots of *Zea* seedlings 2-d-old exposed to white light. This finding was somewhat surprising as violaxanthin and neoxanthin were shown to be present in the light-exposed roots. The possibility still exists, however, that the rate of utilisation of the inhibitor might be so rapid that isolation of significant amounts would be difficult.

Microsurgical removal of the root cap of *Zea* has been shown to prevent the response of the roots to gravity¹⁰ and we have found that this treatment completely releases the roots from the inhibitory effect of light on elongation⁹. We decided, therefore, to determine whether the root growth-stimulatory properties of DIHB in the light were associated with this region of the root. Seedlings of *Zea mays* var. LG 11, 3-d-old and grown in darkness at 25° C on moistened Whatman No. 1 filter paper, were selected in green light for straight roots 20–30 mm long. Tests were carried out in glass Petri dishes 9 cm in diameter containing filter paper and

7 ml of the appropriate solution. Root length was measured immediately following treatment and again after a 4 h incubation period in white light or total darkness. Decapitated and control seedlings (with intact root apices) were placed in contact with distilled water or 0.1 mM DIHB solution. An additional control in which a 1 mm deep vertical incision was made into the root cap was used to establish the effect of injuring the root apex.

Roots of the water control increased in length by 18% and 27% during the 4 h incubation period in white light and darkness respectively, revealing again the inhibitory effect of light (Fig. 2). Decapitation of the roots of the seedlings exposed to white light resulted in an elongation equal to that of dark controls with intact apices⁹. Decapitation of the roots of the darkened seedlings, however, seemed to have no effect on root elongation. As the treatment designed to show the effect of injury to the root apex did not produce an enhancement of elongation, it was concluded that the root cap of *Zea* seedlings is implicated in the light-induced control of root elongation.

Application of DIHB to control and root-decapitated seedlings in the light and dark gave a uniform elongation of 31% to 32% during the 4 h incubation period. It is therefore clear that in presence of DIHB the decapitation had little effect on root elongation. Thus, it seems that the root growth-stimulatory properties of DIHB are independent of the light-induced control system which we have shown to be present in the root cap.

Impact of cool temperatures on transformation of human and armadillo lymphocytes (*Dasypus novemcinctus*, Linn.) as related to leprosy

A CENTURY-LONG search for an unaltered animal in which to study leprosy in humans culminated in the finding that the nine-banded armadillo (*Dasypus novemcinctus*, Linn.), a primitive mammal native to the southern Western Hemisphere, develops disseminated lepromatous leprosy following inoculation with *Mycobacterium leprae* isolated from human tissue^{1–3}. Previous animals only developed leprosy following inoculation with leprosy bacilli after having been immunologically suppressed by neonatal thymectomy with or without irradiation of bone marrow^{4–8}. Yet curiously the leprosy lesions occurred chiefly on the cooler tissues, the footpads.

TABLE 1 Transformation of lymphocytes from 27 normal uninoculated armadillos to PHA at various temperatures.

	37° C		33° C		28° C	
	PHA	CT*	PHA	CT	PHA	CT
Mean	6,970	755	2,402	677	1,351	745

Standard error of mean	367	38	329	38	263	34

Results expressed as an average value of duplicate cultures in c.p.m. of ^3H -thymidine taken up by lymphoblasts.

* CT, control, no PHA added.

Binford and Brand noted that humans with leprosy were most severely infected in the cooler regions of their bodies such as the nose and digits, and so suggested that *M. leprae* may grow better at low temperatures^{9,10}. Storrs first suggested that the armadillo be used for the study of leprosy because its low body temperature (30° C to 35° C) was comparable with the cool regions of humans¹.

We reasoned that such a cool body temperature might depress metabolic activity and from this, cellular immunity of the armadillo might also be depressed and so enable infection by *M. leprae*. To test this we investigated the effect of temperature on the transformation of lymphocytes from armadillos when stimulated by phytohaemagglutinin (PHA) and lepromin.

The transformation of lymphocytes *in vitro* by mitogens is considered a measure of cellular immunity of the individual. More specifically, transformation of lymphocytes by mitogens may reflect the capacity of an individual to respond to and to control certain infectious agents, mycobacteria, brucellae, fungi and viruses, and to reject allografts and neoplasms.

Initially, lymphocytes from 27 normal, uninoculated armadillos were cultured with PHA following procedures previously described¹¹, with the exception that 10% foetal calf serum was used in place of autologous plasma. Armadillos were anaesthetised with ketamine hydrochloride (50 mg kg⁻¹) and 10–15 ml of blood were drawn by intracardiac puncture into heparinised syringes and transferred into siliconised tubes. Lymphocytes were separated and divided into nine equal samples and cultured in triplicate. PHA was added to two of the cultures in each triplicate set and no PHA was added to the third culture which served as a control. One of each triplicate set was cultured at 37° C, the second at 33° C and the third at 28° C, in a humidified atmosphere of 5% CO₂ for 72 h. Lymphocyte transformation was measured by the uptake of ^3H -thymidine. A Packard Tricarb Scintillation Counter measured the results which were expressed as an average of duplicate samples in c.p.m.

The transformation of lymphocytes stimulated by PHA was reduced by approximately 66% when the lymphocytes were cultured at 33° C and by 81% when cultured at 28° C as compared with transformation of lymphocytes at 37° C (Table 1). Thus, a depression of lymphocyte responsiveness to PHA occurred at low temperatures or temperatures comparable with the body temperature of the armadillo.

Second, transformation of lymphocytes by lepromin was measured using lymphocytes from 13 armadillos. We used 0.1 ml of lepromin (containing 3×10^7 sonicated *M. leprae* ml⁻¹) as the specific mitogen, instead of the non-specific mitogen, PHA. The technique was otherwise identical to that used with PHA. Four of the 13 armadillos were uninoculated animals and seven were uninfected, but inoculated with *M. leprae* 30 months before the *in vitro* challenge of lymphocytes by lepromin. The remaining two armadillos which were inoculated with *M. leprae* were grossly infected with leprosy.

A marked reduction of transformation of lymphocytes by lepromin from all armadillos occurred at 33° C and 28° C when compared with transformation at 37° C. Lymphocytes

from uninoculated armadillos which were cultured at 37° C transformed at 5,621 c.p.m. (average) while the lymphocytes from armadillos inoculated but not grossly infected with *M. leprae* were more responsive, transforming at 14,505 c.p.m. (average). This increase in transformation of lymphocytes by lepromin reflects sensitisation of the lymphocytes resulting from inoculation with *M. leprae* 30 months previously. Furthermore, lymphocytes from the two inoculated armadillos with gross evidence of leprosy responded nearly identically to the uninoculated animals. The lymphocytes from the grossly infected armadillos averaged 5,680 c.p.m. This lack of an increase in the transformation response of lymphocytes from infected armadillos following stimulation by lepromin could be explained in several ways.

One possibility is the two infected armadillos were not sensitised following exposure to antigens which were acquired by inoculation with *M. leprae* and that the lack of sensitisation reflected the lack of resistance to *M. leprae* which led to lepromatous leprosy.

A second possibility is that the two infected armadillos were initially sensitised as a result of inoculation of *M. leprae* but later anergy developed similar to that occurring in humans with advanced lepromatous leprosy¹², due to a replacement of lymphoid tissues by invading *M. leprae*. But we are unable to explain why the lymphoblastic transformation response was comparable with that of normal armadillos and not more depressed.

Transformation of lymphocytes from humans was also studied to determine if cool temperatures would depress the transformation of lymphocytes. Heparinised blood (15 ml) was obtained by venepuncture in siliconised test tubes from nine healthy, young adult males and one woman. Three of the male subjects had been exposed to *M. leprae* while working for several years in an infectious diseases laboratory and the woman had worked for 5 yr in a

Fig. 1 The lymphoblastic transformation response of lymphocytes cultured at 37° C, 33° C, and 28° C when stimulated by PHA or lepromin is illustrated. An increase in transformation of lymphocytes is demonstrated to the right. The increase occurred when the lymphocytes were transferred from a 28° C incubator to a 37° C incubator and cultured for an additional 48 h. The c.p.m. is a measure of ^3H -thymidine taken up by transforming lymphoblasts. The average value of the control (no PHA or lepromin) was 998 c.p.m. —, Phytohaemagglutinin; ---, lepromin.

leprosum. The lymphocytes were cultured and stimulated by PHA and lepromin as had been done with lymphocytes from armadillos.

In all instances a depression of transformation of lymphocytes occurred at 33° C and 28° C (Fig. 1). The average value of the control, to which no mitogen was added, was 998 c.p.m. No increase in transformation by lepromin occurred in cultures of lymphocytes from the four human subjects who were previously exposed to *M. leprae* as compared with transformation of lymphocytes from six humans not exposed to *M. leprae*. This finding probably reflects non-sensitising exposure to antigens of *M. leprae* rather than an inability of the subject to become sensitised.

Lymphocytes which had been cultured for 72 h with PHA or lepromin at 28° C were transferred to an incubator at 37° C and cultured for an additional 48 h to determine whether the transformation response could be restored. The transformation response was restored by more than 50% (Fig. 1), thus directly implicating temperature as the agent responsible for the depression of the lymphocyte transformation.

We conclude that cool temperatures probably depress cell-mediated immunity *in vivo* and that such a depression of CMI could explain the susceptibility of armadillos to infection with *M. leprae*. Yet another possibility is that *M. leprae* multiplies best at cooler temperatures because a cool environment is optimal for their multiplication.

But, evidence to the contrary has been recently reported: more extensive multiplication of *M. leprae* *in vitro* has been reported in human macrophages at 37° C than at 33° C (ref. 13). If the optimal temperature for the growth of *M. leprae* is 37° C, then the armadillo's susceptibility to leprosy cannot be explained on this basis because its body temperature is much cooler than 37° C. Our finding of normal appearing thymolymphatic organs in the armadillo further supports that the cool body temperature of the armadillo is probably the significant condition responsible for the immune incompetence of the armadillo to *M. leprae* (D. T. P., G. P. W., E. E. Storrs and C. Gannon, unpublished).

The lepromatous leprosy that develops in the armadillo involves internal visceral organs and tissues that are near the body surface¹. The cool body temperature of 30° C to 35° C of the armadillo enables lesions to develop in viscera, whereas in humans lepromatous lesions are generally limited to superficial cool regions.

Cellular immunity may be modified by changes in temperature, for instance, an increase in body temperature could possibly enhance cellular immunity. The role of fever as a potentiator of cellular immunity against malignant neoplasms and infectious agents needs to be assessed. Furthermore, the impact of cool temperatures also needs to be assessed as related to susceptibility to other infectious agents.

Die-back of *Pistia stratiotes* on Volta Lake, Ghana

ANNUAL die-back of *Pistia stratiotes* L., associated with an epidemic of an aphid-transmitted virus infection whose symptoms are leaf yellowing and brittleness, was recently reported for the Ibadan area of Nigeria¹. It was supposed that similar virus epidemics may have checked the initial outburst of the weed on the Volta Lake in Ghana. We confirm that *Pistia* has died back on the Volta Lake from a maximum cover of about 4% of the lake surface in 1966, 2 yr after the dam was closed, to about 1% now (1973). In recent work on the Pawmpawm arm of the lake we have measured the rate of retreat of *Pistia* mat from the main lake. By marking flooded trees near the edges of the mat, it was possible to survey the limits of *Pistia* in August 1971, April 1972 and in July 1973. These surveys, together with an aerial photograph taken in October 1968 (P. C. Pierce, personal communication) made possible the construction of the map shown in Fig. 1, from which it can be calculated that *Pistia* receded at an average rate of about 7 ha yr⁻¹ over the period of observation.

In 2 yr of regular observations², *Pistia* retreat resulted from disruption of *Pistia* mats by storms in the late dry season (February and March), following several months during which the plants, even in enclosed permanent plots, had been severely weakened by poor growth. Aphids were rare in the populations observed, and there was no evidence that virus disease was of primary importance in causing leaf yellowness or brittleness. Size and rapidity of fluctuation in lake-level and antagonism by other plants, which have been implicated in *Pistia* die-back in other areas^{3,4,5}, also seem to be unimportant on the Volta Lake. Retention time here is 4 yr as against 76 d for Lake Kainji, Nigeria³; in any case, the stranding of plants in the drawdown area

FIG. 1 Die-back of *Pistia stratiotes* on the Volta lake, Ghana.

should favour seed germination⁶ and is therefore unlikely to be responsible for disappearance of *Pistia*. The plant has not been replaced for the most part by any antagonising weed.

Circumstantial evidence suggests that poor growth of *Pistia* during the dry season may result from low nutrient status of the lake-water at this time, because of lack of rain to wash in nutrients from adjoining land. Lake nutrient status is probably improved during the early rains as a result of enhanced mineralisation by re-wetting of previously dry soil⁷, inflow to the lake of nutrients from such mineralisation and, possibly, direct enrichment of the lake by nutrients carried in early rainwater⁷. *Pistia* is known to respond sensitively to substrate nutrient level⁸, and especially to nitrogen⁴ the level of which increases many-fold as a result of re-wetting of dry tropical soils. Explosive growth of *Pistia* on the Volta Lake occurs following the first rains after the main dry season². There is evidence⁹ to show that nutrients such as phosphates have now dropped to less than half the level they reached when the lake was first formed.

The long-term disappearance of *Pistia* from the Volta Lake may be reflecting a change in the nutrient level, and probably also the decay and disintegration of flooded trees which originally helped to anchor *Pistia* mats.

Progress of a breeding project for non-human primates in Colombia

THE International Primatological Society¹ and several recent publications²⁻⁸ have pointed out the urgent need for conservation of non-human primates. The capture of live primates for exportation is a major drain on natural populations and breeding programmes are a vital need which has been emphasised by two recent events. First, the Institute for Development of Renewable Natural Resources in Colombia has established limits and standards for the hunting of non-human primates⁹. Second, a large scale, international research project has been launched through a grant from the US National Institutes of Health to the Institute of Laboratory Animal Resources of the US National Academy of Sciences, which will tackle critical questions of supply and demand, and seek to identify primates which must be bred to meet research requirements¹⁰. (In 1969, 16,295 New World primates and 42,514 Old World primates were sold in the United States solely for research³.) We report here preliminary results of the first attempt at large scale, controlled breeding of New World primates in the natural habitat of an exporting country, and discuss the feasibility of future projects.

In 1967 Mike Tsalickis, an animal dealer in Leticia, Amazonas, Colombia, initiated a breeding experiment with squirrel monkeys (*Saimiri sciureus*), the New World primate most widely used in research. (*Saimiri* constitutes 10–80% of primates exported to the United States from Latin America³.) Between 1967 and 1970, Tsalickis released 5,690 monkeys (1,200 males and 4,490 females, some judged to be pregnant) on Isla de Santa Sofia II which was previously uninhabited by non-human primates. (Three adjacent fluvial islands under Colombian jurisdiction called Santa Sofia are designated Santa Sofia I, II and III.) The monkeys could not leave the island without swimming at least 1 km, and hunting and trapping were prohibited. In 1971 Tsalickis, on the basis of a sample count of females with young, estimated the birth rate at 80%. Assuming no mortality, he calculated the existing population at 20,698^{11,12}.

Santa Sofia II is a 1,000 acre (400 hectare) island in the middle of the Amazon River 33 km upriver from Leticia, formed by fluvial deposition perhaps as recently as 40–50 yr ago. Lakes devoid of trees form one-third of the island which is uninhabited by monkeys. (The level of the river fluctuates nearly 7 m seasonally, more than 90% of the island may be inundated during the peak of the wet season in April and May.) Another third is formed by low areas and the edges of the island which are covered by a successional community including *Cecropia* sp. The remaining third of the island is formed by the central and higher areas which are covered by a more advanced successional stage with a mixed community of non-deciduous trees. About 10% of the island has been cleared for agricultural purposes, including fruit trees (banana and guava) planted for the breeding project. Several areas were sporadically provisioned with fresh fruits and monkey chow to supplement natural food available.

From June to early August of 1972 we conducted a census of the *Saimiri* population on the island. Our primary objectives were: (1) to measure the population as accurately as possible; (2) to make recommendations concerning collection and (or) other aspects of population management; and (3) to demonstrate that multidisciplinary efforts can enhance the value of field studies, and that for projects of this sort they may be essential. In this report we describe briefly our census methods and results and their implications. (We will publish a more detailed report later¹³. In addition a report of a subsequent project conducted independently by R. C. B. on the monkeys of Santa Sofia II is in preparation and will provide further data pertinent to the present discussion.)

Our census procedure was chosen to accommodate the topography, vegetation and seasonal flooding; the behaviour and ecology of *Saimiri*, and the availability of time and personnel. To measure the total population we needed to estimate (1) the number of groups on the island, and (2) average group size. We first divided the island into three workable sections (areas A, B and C), aided by the presence of natural ecological barriers such as permanent large ponds (Fig. 1). We then cut sixty-one trails, forty-five at 100 m intervals and sixteen at 200 m intervals, the distance between trails depending on type of vegetation and resultant local visibility. All our trails were perpendicular to and connected by three trails cut by Tsalickis, and facilitated access to most of the island land mass (Fig. 1). The number of groups of *Saimiri* was estimated by repetitions of a synchronic multi-strip census, whereby four to seven field workers walked blocks of adjacent trails, locating groups, until all the trails in an area had been covered in one continuous period. Data on group size, direction and rate of group movement, group cohesion and intergroup distance were also gathered by each observer to aid in determining average group size, and to avoid counting groups more than once. The average group size was estimated in two ways: (1) by averaging accurate

TABLE 1 Population estimates based on two approaches to group size

Area	Average group size	Average No. of groups	Extrapolation of population estimate
A	41	10	410 (in 42% of land mass)
B			287 (in 30% of land mass)
C			269 (in 28% of land mass)
Total			966

Area	Estimated group size	Average No. of groups	Population estimate
A	50	10	500
B	50	4	200
C	50	3	150
Total		17	850

counts of several groups in area A, the most accessible area; and (2) by using field observation from all three areas. The total population of the island was also estimated in two ways. (a) The population of area A was determined by multiplying its average group size (method (1)) by the total number of groups in that area. Assuming comparable density throughout the island (on the basis of similarity of habitat), we then extrapolated to areas B and C on the basis of land area. The three area populations were then added to obtain the total island population. (b) The total island population was obtained by multiplying the estimated average group size (method (2)) by the total number of groups in all three areas.

Table 1 shows the total island population estimates obtained by the two methods. Method (1) yielded a population of 410 for area A, and a total island population of 966. Method (2) yielded a total island population of 850. Areas A and B were each censused seven times under varying conditions (time of day, weather, composition of observing teams and direction of movement of observers). Area C was censused twice. Approximately 350 man hours were spent in direct censusing. The variability in number of groups sighted was low (s.d. = 1.13), indicating relative consistency and lending confidence to the method. (Continuing field research by R. C. B. on Santa Sofia II generally supports the number of resident groups estimated during the summer of 1972.) We therefore conclude that the *Saimiri* population of Isla de Santa Sofia II as of August 1972 was between 850 and 966. Based on variance in our counts (s.d. = 1.13), the probability that there were more than 1,200 or fewer than 550 monkey on the island is less than 0.0001.

Our results have two possible interpretations: (1) if published estimates are reliable¹¹ there was a decline from 20,698 to 850-966 in 18 months, or (2) previous estimates are unreliable. We are not aware of any unusual or altered conditions such as flooding or disease which might account for such a drastic mortality during the 18 month interval, nor

has Tsalickis indicated such conditions. Previous estimates of population size were based on too little evidence and even then were too optimistic because the calculations assumed no mortality. In either of the interpretations census figures must be viewed in relation to the documented number of animals introduced to the islands (5,690). Substantial decline is evident.

We can only speculate as to causes of mortality, particularly since there is no way of knowing when and over what period the decline occurred. Nevertheless, clearly many important aspects of *Saimiri* behaviour and ecology were not known or not taken into account when this breeding experiment was planned. Factors that need to be considered include abundance of food, spatial requirements, predator pressure, disease, climatic change, consequences of introducing alien groups of unfamiliar and unrelated individuals, and the effects of a continued influx of new animals on established groups.

M. Tsalickis has communicated his personal conviction that large numbers of monkeys were stolen from the island for sale in Leticia. The only evidence of poaching of which we are aware was reported to us by T. Jerkins of Tarpon Zoo, Tarpon Springs, Florida. In October 1972 an unspecified number of monkey traps were discovered on the island by Tsalickis' employees. On February 26, 1973 a tattooed monkey from the island was discovered in a shipment to the zoo. This is evidently one of the animals introduced to the island when only a small portion were tattooed. (No tattooed monkeys were found in the 1972 census and the subsequent study by R. C. B.) On the basis of present information, we consider the poaching hypothesis both unverified and unlikely, although it cannot be excluded as a possibility.

The single most important lesson to be learned from the Santa Sofia experiment is that controlled breeding of non-human primates on a large scale cannot be accomplished without considerable basic biological data to support careful planning and management—even when such projects are conducted in apparently representative habitat within the natural range of a species. The successful breeding of *Saimiri* in the enriched tropical hammock of the Monkey Jungle, Miami, Florida, has indicated that controlled breeding of certain non-human primates in a natural or seminatural environment is possible, when careful management, including daily dietary supplementation, is provided. Although they live in only a 4 acre area, the squirrel monkeys of Monkey Jungle increased from thirty-seven animals to approximately 150 in 6 yr. The original thirty-seven were handpicked and in apparent good health. The population was fed seven times a day, 7 d a week, to supplement the natural diet¹⁴. In this connection it is important to note that Monkey Jungle is a commercial zoo and not a primate ranch. For that reason, and in spite of its success, it cannot answer unequivocally the question of whether or not *Saimiri*, or any other species, can be bred economically, that is, at prices competitive with current sources of non-human primates.

The *Saimiri* breeding project of M. Tsalickis on Santa Sofia II is provisionally licensed as a Zoo-Criadero (faunal breeding farm) by the Division of National Parks of INDERENA. Tsalickis' effort has paved the way for future primate ranching attempts, and continued studies on Santa Sofia will help determine more of the critical factors in *Saimiri* husbandry. Finally, the Santa Sofia experiment has again emphasised the practical need for more data on the behaviour and ecology of non-human primates. Such data are essential for the economical, large scale husbandry which must be achieved if many species are to avoid depletion in nature and are to be preserved as a renewable natural resource.

We thank B. Harrison for financial support and for supervising the project, except field work and M. Tsalickis for help

Tobacco smoking and a 'stimulus barrier'

ONLY one in four smokers who wish to stop, actually succeed¹. The strength of the habit is hard to explain in terms of learning theory, since its manner of reinforcement is uncertain. This study considers a possible mechanism through which smoking might be positively reinforced².

Freud³ described a perceptual function which enables us to select from an overwhelming mass of sensory data only those aspects of the environment which have meaning or

significance. In this way, a large sector of potential sensory input is 'blocked out'. He therefore conceived this function as a stimulus barrier; 'a special integument or membrane which keeps out the stimuli'. Relative failure of this 'barrier' is unpleasant, and part of common experience. Irrelevant sounds intrude into consciousness, and are irritating.

This 'barrier' can be conceived in terms of neurophysiological models for the habituation of the orienting response⁴. The orienting response consists of a number of behavioural and physiological changes induced in the subject by a novel stimulus. This response diminishes and ultimately ceases after a number of repetitions of the stimulus. The individual is then said to have habituated to that particular stimulus. A new stimulus re-evokes the orienting response, causing dishabituation. It is not unreasonable to suppose that the phenomenon of habituation reflects an individual's ability to 'block out', or to selectively not attend to irrelevant stimuli. The possibility that smoking may increase the effectiveness of a 'stimulus barrier' was examined by a study of the habituation of the orienting response in smokers.

The subjects were 10 young men (20–25 yr of age) who habitually smoked at least one packet of cigarettes a day. Alpha-desynchronisation of the electroencephalograph was the aspect of the orienting response chosen for study, since the peripheral effects of nicotine may have altered the galvanic skin response, which is more usually chosen.

The EEG was recorded in a sound-damped room. An active silver-silver chloride electrode was set at the vertex (cz on the international 10/20 system) and referenced to the left mastoid. The subjects were tested on four occasions at three week intervals. The first session involved familiarisation with the recording procedure. Two series of stimuli were presented through loud-speakers 2 feet from the subjects. The first series consisted of twenty loud (90 dB) brief (0.5 s) bursts of pure tone (2000 Hz) with interstimulus intervals varying between 30–80 s. The second series differed only in that the frequency of the tones was 1000 Hz. Each series ended with a dishabituating tone of 10 s duration. The habituation point was defined as the number of stimuli at which the EEG showed no desynchronisation to a stimulus, when there was also no desynchronisation to the two succeeding stimuli.

The percentage of alpha activity was determined between the fifteenth and sixteenth stimuli, and done after the recording session by one observer who was unaware of the smoking conditions. Skin resistances were recorded as described elsewhere⁵, and the heart rates taken by means of cardiometer coupler (9857) on an Offner-Beckmann dynograph.

Before the second session, subjects were instructed to smoke according to their usual pattern. The 2000 Hz series of tones was presented while the EEG was recorded. Forty-five minutes later, subjects were instructed to smoke two cigarettes of their preferred brand and were then presented with the 1000 Hz series of tones. The mean duration between the last cigarette smoked before the session and the onset of recording was 31.1 min, s.e. 3.1, with a range of 20–50 min.

Before the third session, subjects were instructed to abstain from cigarettes for 12 h. The two series of tones were again presented, one before smoking, and the second after smoking two cigarettes. The fourth session was identical to the third except for the substitution of a nicotine-free placebo cigarette (roasted chicory leaves in authentic cigarette packing) instead of the preferred brand. The subjects were told the cigarettes were 'foreign', and none of them realised that they were not smoking tobacco.

The results (see Table 1) indicated that the immediate effect of tobacco smoking was to greatly increase the speed of habituation, and that placebo smoking had no effect.

Thus, in the second session, the mean habituation point changed from 16.1–4.5, after smoking (paired $t = 7.74$,

TABLE 1 Means and standard errors for habituation point, heart rate, skin conductance and proportion of alpha

		Session 1 (Training, series 1)	Session 2		Session 3		Session 4

* Although all 10 subjects participated in all tests, some readings had to be discarded due to recording problems.

$P < 0.001$) and in the third session, when the subject smoked after 12 h deprivation, the mean habituation point changed from 13.8–5.6 (paired $t = 4.62$, $P < 0.005$). On the other hand, during the placebo smoking session the mean habituation point remained virtually unchanged 14.7–13.7 (paired $t = 0.92$).

Delayed consequences of smoking were not manifest in habituation rate since there was no difference between the rates after a period of normal smoking and after a 12 h deprivation. The mean habituation point before smoking in the second session was 16.1, while the mean habituation point after deprivation was 14.3 (paired $t = 1.14$).

Occasional failures to show a dishabituating response were evenly distributed between tobacco-smoking and placebo-smoking sessions.

Since the change in habituation was not found with placebo, it seems likely that the effect was mediated by a drug, presumably nicotine, rather than by psychological factors. Increase in speed of habituation usually reflects diminished arousal, and drugs which effect such a change are therefore considered to be sedative⁶. Nevertheless, the immediate effects of smoking on habituation cannot be adequately explained in terms of sedation, since this is not reflected in measures of arousal.

Changes in peripheral measures of arousal suggested that smoking may cause mild central nervous system excitation rather than sedation. The skin conductance tended to rise, while a significant increase was shown in heart rate during session 3 (paired $t = 5.52$, $P < 0.001$). This increase was not apparent in session 2 (paired $t = 0.90$). There was also a significant difference between the heart-rates of deprived and non-deprived subjects before smoking (paired $t = 4.87$, $P < 0.001$). These changes, however, may be purely autonomic and not be correlated with cerebral events. Nevertheless, they are consistent with certain previous electroencephalographic evidence^{7–10}, although in the present study no significant change in proportion of alpha activity was induced by smoking (paired t in session 2 = 1.27, and in session 3, $t = 0.69$).

Theoretical models of the habituation phenomenon suggest that it depends upon active inhibitory mechanisms⁴, of which a number have been described^{11–15}. Clinical studies involving habituation and measures which are likely to reflect central nervous system excitation, suggest an inverse relationship between 'inhibitory' and 'excitatory' processes¹⁶. It therefore seems not impossible that tobacco smoking causes a dislocation of the usual relationship, so that inhibitory mechanisms are stimulated without simultaneous reduction in CNS excitation.

In conclusion, the findings suggest a possible means of positive reinforcement of tobacco smoking through its effect upon the individual's manner of screening of sensory input.

Reaction of methyl mercury with plasmalogens suggests a mechanism for neurotoxicity of metal-alkyls

THE biosynthesis of methyl mercury from mercuric ion, by microorganisms which live in sediments polluted with mercury, is of special significance to the bio-accumulation of mercury^{1–3}. Although the mechanism of methyl mercury biosynthesis is understood to a large extent at the molecular level^{4–6}, very little is known about the mechanisms of molecular interaction in both the bio-accumulation and the neurotoxicity of this compound. It is clear that ingestion by humans of food contaminated by methyl mercury leads to

FIG. 1 *a*, 220 MHz NMR spectrum of plasmalogen. *b*, 220 MHz NMR spectrum of the products formed when plasmalogen is incubated with methyl mercury chloride and water.

the synthesis of methyl mercury chloride in the stomach, and this, being very non-polar, is easily transported into the blood stream⁷. The distribution of methyl mercury in animals is characteristically different from that of inorganic mercury, in that alkyl mercury compounds have a tendency to partition into the lipids, or hydrophobic regions of the cell⁸.

Post mortem examinations of victims of the Minamata disaster, who suffered neurological disease after eating fish contaminated with mercury, revealed extensive damage to the central nervous system. Widespread lysis of cell membranes, especially of neuroglia and granule cells, was reported^{9,10}. Methyl mercury in aqueous systems is an unreactive molecule, and it is hard to see how it could cause such irreversible damage. Although methyl mercury reacts readily with sulphhydryl groups, it does not form stable complexes with nitrogen-containing bases in aqueous solution; in fact it does not complex with pyridine in aqueous solution¹¹.

It is possible that the reaction of methyl mercury with cysteine residues, which are present at the active sites of several important enzymes of the glycolytic pathway, could provide a basis for the neurotoxicity of this compound¹². Concentrations of methyl mercury greater than catalytic concentrations would have to be present, however, to be effective in enzyme inhibition. As the binding of methyl mercury to thiols is reversible, relatively large concentrations of methyl mercury would be required for that enzyme inhibition. Furthermore, inhibition of the enzymes in the glycolytic pathway would have an indirect and reversible effect on membrane synthesis. We report here that methyl mercury can react both catalytically and directly with a

FIG. 2 Structure of plasmalogen with 220 MHz NMR proton assignments in δ (p.p.m.) adjacent to each carbon atom.

FIG. 3 High resolution mass spectra of the 2,4-dinitrophenylhydrazine derivatives isolated from the reaction products of the methyl mercury-catalysed hydrolysis of plasmalogen. Spectra were recorded at 10 eV and at 70 eV (inset).

group of phospholipids which are important in membrane structure for cells of the central nervous system.

High resolution nuclear magnetic resonance (NMR) has been used to assign all the protons of a plasmalogen (L α phosphatidyl ethanolamine), which has palmitic and stearic acid as alternative residues to the vinyl ether linkage at the α' carbon, and linolenic as the unsaturated fatty acid at the β carbon. Methyl mercury chloride is soluble in this phospholipid, and the methyl mercuric ion catalyses rapid hydration and hydrolysis of the vinyl ether linkage to give a mixture of palmitic and stearic aldehydes plus the linolenic monoglyceride product. The course of this reaction was followed by 220 MHz NMR, and the aldehyde products were characterized further by mass spectrometry of their 2,4-dinitrophenylhydrazine derivatives. The relevance of this reaction to the neurotoxicity of metal-alkyls is probably linked with membrane lysis, which is specific for those membranes which contain plasmalogens as a major constituent of the phospholipid backbone in membrane structure.

Reaction mixtures were set up containing 24.1 mg of plasmalogen (phosphatidyl ethanolamine obtained from P-L Biochemicals) dissolved in 1.0 ml of CD_2Cl_2 to which 163.5 mg of methyl mercury chloride was added. When 0.17 ml of water was added the reaction proceeds at 25°C to yield palmitic and stearic aldehydes. We used a concentration of methyl mercury chloride twenty times greater than that of plasmalogen, but the catalytic nature of the reaction makes it possible to use much less. Decreasing the concentration decreases the rate of catalysis without altering the stoichiometry for the reaction.

Fig. 1 shows the 220 MHz NMR spectra of the plasmalogen before and after addition of methyl mercury chloride. From the spectrum in Fig. 1*a* it is possible to assign all the protons in this mixture of compounds. Fig. 2 shows the basic structure of the plasmalogen with resonances assigned in δ (p.p.m.); using tetramethylsilyl as an internal standard. The spectrum in Fig. 1*a* was integrated and the plasmalogen structure confirmed by these NMR data. Resonances of special interest in the overall reaction with methyl mercury chloride are those due to the protons of the *cis* double bond of the vinyl ether linkage which are assigned at $\delta = 4.35$ and $\delta = 5.89$ respectively (Figs 1*a* and 2). Also the resonance at $\delta = 8.18$ which represents the protons of the primary amine of ethanolamine is interesting because this resonance shifts from $\delta = 8.18$ to 8.07. This shift is indicative of a weak interaction between methyl mercury and this basic amino group; an interaction which does not occur in aqueous solution. Therefore, the hydrophobic nature of the phospholipid facilitates coordination to nitrogenous bases to some extent. When methyl mercury chloride is added to the plasmalogen, the vinyl ether resonances at $\delta = 4.35$ and $\delta = 5.89$ decrease in intensity and a new resonance which is characteristic of the presence of a long chain aliphatic aldehyde appears at $\delta = 9.69$ (Fig. 1*b*).

Fig. 4 Proposed reaction sequence for methyl mercury-catalysed hydrolysis of plasmalogen.

The aldehyde products formed in this reaction were characterised as their 2,4-dinitrophenylhydrazone derivatives. The reaction products from the NMR experiment were transferred to a reaction vessel and allowed to react with 1.0 ml of 0.2% 2,4-dinitrophenylhydrazine in 2N H_2SO_4 . The reaction was allowed to proceed for 1.5 h and then the products were extracted into chloroform. The chloroform layer was dried over anhydrous sodium sulphate and evaporated to dryness. The yellow residue was dissolved in 0.5 ml of benzene and applied to a silica gel column (2 cm \times 17 cm). The column was eluted with benzene, and 5.0 ml fractions were collected. Two yellow compounds were eluted from the column, and the first fraction to elute was evaporated to dryness and subjected to mass spectrometry (Fig. 3). Molecular ions at m/e 420 and m/e 448 are consistent with the product being a mixture of palmitic and stearic aldehyde 2,4-dinitrophenylhydrazones. The fragments at m/e 385 and m/e 413 are due to the loss of H_2O and OH from the palmitic and stearic derivatives respectively. The peaks at m/e 224 and 206 are due to McLafferty rearrangements involving three carbons of each aldehyde chain, and the 2,4-dinitrophenylhydrazone portion of each derivative¹³. The rest of the fragmentation pattern is consistent with that of a mixture of C_{16} and C_{18} saturated aliphatic carbon chains.

High resolution NMR is especially valuable for the study of the structure and reactivity of phospholipids in solution because all the protons for these complex molecules can be assigned. We have shown that methyl mercury reacts catalytically in promoting hydration and hydrolytic cleavage of the vinyl ether linkage in plasmalogens to give a mixture of long chain saturated aldehydes. A sequence for this reaction is proposed in Fig. 4. The fact that methyl mercury is soluble in phospholipids, and causes lysis of certain cell membranes in the central nervous system makes it tempting to speculate that this reaction could have significance in the neurotoxicity of this metal-alkyl. Also, it is expected that other metal-alkyls should catalyse this reaction by a similar reaction sequence.

GENERAL

Hydrogen fuel

HYDROGEN is receiving much attention as a clean fuel¹⁻⁴. It is usually stated or implied that hydrogen is a clean fuel because only water is produced when hydrogen is ignited in an engine. Unfortunately, this is not a fact. The following reaction also occurs:

Furthermore, as energy is extracted from the reaction as work, the reaction favours the production of more hydrogen peroxide.

A one-cylinder Briggs and Stratton engine was equipped with a propane-type carburettor, and the muffler was replaced with a stainless steel water-cooled condenser 3 feet in length. A dual feed system enabled it to be started using propane. When the engine had reached 1,750 r.p.m. and was running smoothly, the fuel was slowly changed from propane to hydrogen while the engine speed was maintained. After the engine had been running on pure hydrogen for 10 min the condensate from the exhaust was collected and analysed for H_2O_2 .

Qualitative tests with $\text{TiOSO}_4\text{-H}_2\text{SO}_4$ solutions and with Tes Tape urine sugar analysis paper indicated a strong positive for H_2O_2 . The concentration was analysed using a standard KMnO_4 titration. The results of three separate runs are given in Table 1.

TABLE 1 Concentration of H_2O_2 in the exhaust of an engine using H_2 gas as a fuel

Test No.	H_2O_2 in the exhaust (p.p.m.)
1	230
2	220
3	220

Although the concentration of H_2O_2 in the exhaust was not high in these experiments, the implications of using a large number of big engines producing H_2O_2 in the environment must be considered. Hydrogen peroxide is known to generate free radicals which would be a potential hazard if inhaled. If they are to be completely safe, engines operating on hydrogen gas will probably require some type of catalytic converter for the exhaust gases.

book reviews

Men from beyond Mars

Communication with Extraterrestrial Intelligence. Edited by Carl Sagan. Pp. xx+428. (MIT: Cambridge, Mass. and London, November 1973.) \$10.

IN sight of Mount Ararat, reputed resting place of Noah's Ark, scientists from six countries met to confer on "Communication with Extraterrestrial Intelligence" (CETI) in September 1971. The 54 delegates concluded: "It seems to us appropriate that the search for extraterrestrial intelligence should be made by representatives of the whole of mankind".

This volume is a transcript of the conference, which was held at the Byurakan Astrophysical Observatory in Soviet Armenia. The observatory's director, Viktor Ambartsumian, was chairman of the Soviet delegation.

The first-ever CETI conference was an unofficial gathering at Green Bank, USA, in 1961, at which Frank Drake presented the now classic formula for calculating the probability of communicative life in the Galaxy, which has since been discussed and elaborated in various papers and books. More than half the Byurakan proceedings consist of a wide reassessment of the many implications in the formation of planets, origin of life, rise of intelligent life and the desire to communicate. Contributors to the debate include Francis Crick, Tom Gold, V. I. Moroz, Leslie Orgel and Y. N. Paryisky.

Surprisingly, the Byurakan estimate differs little from previous suggestions. "We have estimated the rate of formation of such civilisations in the Galaxy: one is formed about every 10 years", says Carl Sagan, the United States delegation's head, in summary of the debate.

Yet the problem of estimating the lifetime of such a civilisation remains the greatest unknown in any such calculation: "If civilizations destroy themselves shortly after arising, there may be no one for us to talk to but ourselves", says Sagan. Canadian anthropologist Richard Lee argues for the positive effect of CETI on a civilisation: "If we receive a communication we want to stick around to see what the reply is".

"There are a million technical civilisations in the Galaxy. This corresponds roughly to one out of every hundred thousand stars", Sagan concludes cautiously on page 166, freely admitting the possible massive error in this figure. A

few pages on, Sebastian von Hoerner makes his own estimate—600 light years—of the distance between current communicative civilisations.

Startling news to come later in the conference was V. S. Troitsky's revelation (page 256) that the Andromeda galaxy and 11 stars near to Earth, including Tau Ceti and Epsilon Eridani, had been monitored in autumn 1968 for artificial signals. This was the first attempt since Drake's project Ozma to eavesdrop on stars. A proof note is added to outline the recent similar work of G. Vershuur (*Icarus*, 329; 1973) and another United States project. All such projects have had negative results.

Recently, N. S. Kardashev and Troitsky have reported possible artificial signals from space, breaking Iosef Shklovsky's rule of thumb presented at Byurakan: "We must follow the legal principle of presuming signals natural until proved otherwise".

Several papers have already been spun off from discussions and presentations at the CETI conference, including one by Sagan (*Icarus*, 350; 1973) which is reprinted as an appendix. Also previously published are Freeman Dyson's free-ranging presentation to Birkbeck College in 1972, *The World, The Flesh and The Devil*, and the CETI conference resolutions (*Icarus*, 412; 1972).

Another topic discussed at Byurakan was astroengineering—large-scale projects of advanced civilisations that might produce tell-tale signs such as extensive amounts of infrared emission. Techniques of contact with extraterrestrials were outlined, with Bernard Oliver summarising the project Cyclops report (NASA CR 114445). Should such an expensive undertaking be funded? Oliver is in no doubt: "All past human history may indeed be merely a prelude to an inconceivably exciting future as participants in a galactic culture".

Linguist B. V. Sukhotin reveals the development of a decoding programme, in a short section on the possible contents of extraterrestrial messages. Then follows a brief discussion involving historian William H. McNeill on the consequences of such contact. "We need from the beginning to accept responsibility for the effect of what we may be planning", says Philip Morrison. Sagan and Morrison have since taken part in another discussion on ETI with participants including a theologian, a philosophical viewpoint not represented at Byurakan.

The conference resolutions outline a number of directions for future research, and suggest new radio and infrared instruments to aid the search. (The Soviet 600 m radio telescope to be opened soon will be partly used for CETI research.) "All of the instruments described above have the capability of providing important data in subjects quite separate from CETI", the participants point out.

But it was Shklovskii who summed up their main problem: "All the natural sciences rely upon observations and experiments. We have none of that here".

IAN RIDPATH

School to college

Continuity and Discontinuity: Higher Education and the Schools. Pp. xi+116. (A Report and Recommendations by the Carnegie Commission on Higher Education, August 1973.) (McGraw-Hill: New York and London, October 1973.) £2.95.

REPORTS on education are not, as a rule, noted for their attractive reading. This one is an exception, partly on account of its stimulating and imaginative mode of presentation, and partly because of the fascinating light it throws on some of the more intransigent educational problems that face us in Britain today. It is sometimes comforting to see one's own difficulties painted larger than life in the colours of another country. Chapters 2 and 3 of the report provide a condensed history of American educational evolution dating from 1850 and projected into the year 2000. Some outcomes are an emphasis on the need for more closely coordinated admissions policies from school to college, the need to experiment with D. Arts degrees as teaching alternatives to the PhD, and the necessity for revised and more standardised testing procedures. Chapters follow on the reform of the admissions procedure to college, improvements in secondary education, new structural patterns relating to such factors as course content, the education of school teachers and administrators, and possible mechanisms for better school-college collaboration. Chapter 1, being a statement of major themes and recommendations, seems somewhat out of place and would have been better at the end as an outcome of all that had gone before.

Several sections of the report are of particular interest at the present time:

for instance, a scheme for shortening the length of the college course to produce a BA qualification somewhat similar to our proposed Dip.HE. It is interesting to be told that teacher education is now regarded as the largest single enterprise in American higher education. Clearly, many of the problems in this field, with the teacher training curriculum, teaching practice arrangements in schools, and in-service training closely parallel our own.

The report will thus be of interest to anyone concerned with the planning of secondary or higher education. Reading it, I could not help but feel profoundly thankful that Britain is a relatively small nation with a public examination system and entry requirements to higher education subject to some degree of central control and hence an equivalence of standards.

W. H. DOWDESWELL

Glimmer of hope

Priorities for Action: Final Report of the Carnegie Commission on Higher Education, with Technical Notes and Appendixes. Pp. x+243. (McGraw-Hill: New York and London, October 1973.) \$4.95.

THE ability of the British to look into their future by looking into the American present has been disturbed by the advent of instant communication, through which the American present influences not only their future but also their present. They therefore face the paradoxical situation that while in the sphere of mass higher education they have not yet caught up with the United States of the 1950s, they share in the disillusionment and graduate employment problems of the 1970s. "A traumatic loss of sense of assured progress has occurred (page 6) the world over, and as a result the British are in danger of accepting their inferiority to the educationally developed nations permanently and disastrously. The report, with its dispassionately balanced outlook, provides an effective antidote to this policy of despair.

"In 1870, the issue was the modernisation of higher education—how to adjust to industrial and agricultural expansion, to political populism, to the rise of science. To-day the issue is more the humanisation of higher education—how to respond to the greater aspirations of more individuals for a higher quality of life, how to adjust to the social facts of more affluence and more leisure, how to incorporate into higher education the rise of the creative arts." (page 21.)

"One of the interesting—and, to some, surprising—discoveries of recent times has been that quality and quantity are

not necessarily inconsistent with each other in the academic world". (page 27.)

"We have suggested special admission provisions for disadvantaged students where their ability and the special assistance of the College will make possible their meeting, in full, the academic standards of the college within a reasonable period of time and certainly by graduation. Remedial work will be necessary." (page 37.)

"Planning for the future of higher education should be on a contingent basis, subject to constant re-examination. . . . The technocratic planning analysts are bound to be wrong." (page 80.)

Finally and rightly, the report quotes Ashby's remark about the need to preserve the "thin clear stream of excellence" (page 30). But are we always sure that in pretending to protect excellence we are not protecting privilege?

The editor has restricted me to 400 words, and within that compass I cannot do justice to this remarkable report. The purpose of the disconnected quotations above is to persuade politicians and civil servants, industrialists and businessmen, academics and students, to read this remarkable report whole and to take heart from it.

L. R. B. ELTON

Pacific problems

Nature Conservation in the Pacific. Edited by A. B. Costin and R. G. Groves. Pp. xvi + 337. (Proceedings of Symposium on Nature Conservation in the Pacific of 12th Pacific Science Congress held in Canberra, August–September 1971.) (Australian National University Press: Canberra, April 1973.) \$12.50.

LIKE most other conference proceedings, this book has taken an unconscionable time to produce. Yet since Dr Lee Talbot says on page 261 that "relatively little progress on conservation problems has occurred in the South-east Asian region" since the Bangkok Conference of the International Union for the Conservation of Nature in 1965, perhaps this does not matter much. Nature conservation problems seem to be either static or dynamic in the wrong direction. For Dr Talbot goes on to add that most of the same problems that existed in 1965 are still problems, some of them considerably aggravated, while a whole range of new problems have appeared.

Although the subjects covered by the symposium are wide ranging, the eastern Pacific is almost wholly omitted, the northern Pacific is grossly underplayed, and Australia and its neighbouring region bulk as large as one would expect from the locale.

Many of these papers are excellent, but I wonder whether it is useful to the scientific community to have them all

printed, after an undue delay, in book form? Would it not be better to have an abstracting service for these conferences and symposia, widely circulated soon after the event, and enabling people interested in particular papers rapidly to get a copy?

RICHARD FITTER

Drug receptors

A Guide to Molecular Pharmacology-Toxicology. Edited by R. M. Featherstone. Part 1: pp. xiv+425; part 2: pp. xiii+426–811. (Modern Pharmacology: 4 series of Monographs and Textbooks, vol. 2.) (Dekker: New York, September and November 1973.) Part 1: \$29.50; part 2: \$18.75.

MOLECULAR biology, it is said, owes its origins in no small part to the application of novel physical and chemical techniques to biological problems. These books are intended to go one step further, by describing how several of the newer techniques of molecular biology are being used to solve interesting and important problems in pharmacology and toxicology. They contain a collection of 21 chapters by a total of 30 authors, each chapter devoted to model systems, methodology, or both. As the editor says, there is no great thread of continuity among the chapters and none was intended. Nevertheless, the books are aimed pretty squarely at proteins as drug receptors: witness the contorted sausage on the dust jacket and the categorical statement on page 308 that "whenever a drug receptor has been identified, it turned out to be a protein". (Workers on actinomycin beware!) This no doubt explains why there is no treatment of molecular interactions between drugs and nucleic acids, which to my biased view seems rather a pity.

In part I the first three chapters, on model membranes, sugar transport receptors and ultrastructural studies, provide a useful and balanced introduction to the next four which are largely concerned with receptor identification and isolation, the prospects for which are succinctly stated in the quotation from Professor Burgen at the head of chapter 4. Here is a mine of valuable information about progress in several important areas which will commend itself to many a graduate student embarking on research. There follow three chapters concerned with conformational changes induced in proteins by drugs, the molecular pharmacology of acetylcholinesterase, and enzyme kinetics in the service of studies on structure-function relationships.

The scope of Part 2 is broader, with more concentration on the application of physical methods and mathematical

approaches to pharmacological problems. It is noteworthy that several authors of the more theoretically-based chapters are at pains to put their contributions into historical perspective and to emphasise that their calculations are intended to complement, but in no way replace, experimental investigations. There are chapters on nuclear magnetic resonance, electron spin resonance, optical activity, molecular orbital theory, and thermodynamics as applied to the study of drug-protein interactions. Another three chapters deal with anaesthetics, including the noble gases, primarily from the standpoint of discussing intermolecular forces involving simple drug molecules. They are reinforced by another chapter outlining the use of genetic variants to help probe the sites of action of inert anaesthetic gases and the binding of oxygen to haemoglobin. The two remaining chapters concern the induction of specific proteins by steroid hormones and the relative usefulness of lipids and proteins as models for studies in molecular pharmacology.

Notwithstanding delays caused by the failure of one author to deliver the goods (and he is accorded most commendably charitable treatment by the editor in his preface) there is evidence that a real effort was made to publish these books as promptly as possible. The bibliographies are sufficiently full to give the reader ready access to much if not most of the primary literature, but the rudimentary nature of the subject index places severe limitations on the value of the work as a reference source or guide. There is a much larger author index, but this is of limited value except as a means of verifying that a particular author's work has been cited. The intention is, however, clear enough that this publication is conceived as a collection of self-contained essays and in that light it will serve a useful purpose. Its appearance in two parts is in keeping

with the idea that each part may stand alone, but since no index is provided in part 1, and pages in part 2 are numbered to follow consecutively those of part 1, the two books are not so much companion volumes as moieties of a single work. The price seems rather high, particularly for part 1, but no doubt remains within the budget of libraries and our more affluent colleagues.

MICHAEL WARING

Industrial research

Co-operative Research in Industry: An Economic Study. By P. S. Johnson. Pp. vii+232. (Robertson: London, April 1973.) £4.

THE cooperative research associations have been a relatively neglected sector of the British R and D system. From their inception they have had to struggle hard for their existence and 14 have failed to survive. Their financial basis has always been somewhat precarious, as governments have usually striven to reduce their own contribution and persuade industry to cough up more. Industry, on the other hand, has been generally reluctant to increase its share, partly because of competitive considerations which militate in favour of captive in-house R and D, and partly because of backward attitudes. Only during and shortly after the two world wars did a more generous and far-sighted approach prevail. The RAs indeed owed their very existence to the first world war, which demonstrated forcefully the extent to which some branches of British industrial technology had fallen behind German competition.

The RAs have also been relatively neglected by economists. Not since Edwards's book in 1950 has there been any serious scholarly discussion of the fundamental economic problems of co-

operative industrial research in a capitalist competitive economy. Johnson's modest but highly competent book is therefore extremely welcome. It is especially valuable because it sets the problem firmly in a historical context, permitting one to assess the oscillations in government policy in a long-term perspective. In addition to the two introductory historical chapters, the book includes a valuable statistical survey of RA expenditure in each branch of industry and of the detailed breakdown of RA activities, with many useful tables. The chapters on economic analysis are complemented by the results of a field survey on the views of company research directors, particularly in relation to the growth of contract research. Finally, there is a very brief chapter on RAs in Europe and the United States. This is by far the weakest chapter in the book, which is a pity, as international comparisons would be particularly valuable in view of the growth of EEC-based industrial research.

In his conclusions on methods of financing RAs, Johnson generally welcomes the recent trends which he has demonstrated in his analysis, particularly the growth of contract finance, the switch from general government grants to specific government grants, and the trend towards payment for particular services, such as technical information, testing and so forth. Though his analysis is well argued and generally sound, and also reflects the views of many RA members, my own view is that he may perhaps be missing the wood for the trees to some extent. His survey shows fairly conclusively, as others have also shown, that most RAs are providing some very useful infrastructural technical services, particularly technical information, abstracting and translation services, standards, testing and safety work. They also do some very useful background research which benefits these activities and the research programmes of member firms. In these circumstances, though the extension of contract research is certainly welcome, it does seem to me that cheese-pairing on the small amount of government support for the RAs can be carried too far.

My main criticism of what is otherwise an admirable book is that Johnson does not relate his study of the RAs sufficiently to the general context of government policy for British industrial technology. The failure on the part of some governments to recognise their inescapable responsibility for the health of British science and technology, the efforts to dodge this responsibility in 1970-1972, the lack of a consistent policy for government laboratories and other aspects of the industrial science-technology system are an essential

Wanted: prolific big name

Nature receives many more books than it is able to review, but book publishers accept this and do not seem to withhold books which will not necessarily get reviewed. In certain cases of very expensive books or very small publishing companies, the publisher will make an informal enquiry about whether the book will be likely to be reviewed, since the expense of sending a copy for it not to be reviewed may be less easily bearable.

Recently, however, we have received a press release from a very large publisher on two books on the history of astronomy due later this

year. The aim is a "luxurious quality" of production and, quaintly, they can only be offered as a limited edition because of, among other reasons, "the wealth of illustrative material in the text and the nature of the subject".

The two books are £15 for 400 pages and £30 for 800 pages—not an outrageous price for well illustrated books, but "you will appreciate that the number of review copies... is very restricted. It will help us to judge between conflicting claims if you can specify the reviewer's name and the space you are prepared to devote".

background to the somewhat miserly approach to the RAs. Consequently, Johnson never asks how it was possible for successive governments to squander over £1,000 million on Concorde, while they were making great efforts to save a few hundred thousand pounds on the RAs. But this is the question which must be asked if we are to get value for money from government expenditure on R and D, if British industry is to be able to compete in the 1980s, and above all if British science and technology are to contribute substantially to the improvement of the quality of life for most people in these islands.

C. FREEMAN

Superconductive magic

Superconductive Tunnelling and Applications. By. L. Solymar. Pp. xii+406. (Chapman and Hall: London, June 1972.) £8.00.

THE story has all the ingredients of scientific legend: The phenomenon of superconductivity was discovered in 1911, but nearly half a century of effort by many of the leading lights of theoretical and experimental physics was required before it was well and truly understood. A necessary but not sufficient condition was the invention of quantum mechanics; an almost immediate consequence of that invention was the uncovering and elucidation, as early as 1928, of the phenomenon of tunneling. Not until the early sixties, after the development of a successful microscopic theory of superconductivity by Bardeen, Cooper, and Schrieffer, were these two phenomena brought together. And, lo, there materialised a veritable cornucopia of scientific fruit, with implications and applications ranging from purest physics to manifestly relevant technology. Moreover, the principal architects of this fertile union, Ivar Giaever and Brian Josephson, were mere students, not yet ordained in the doctoral priesthood of science. We have recently seen their achievement crowned with the Nobel Prize, hard on the heels of the same laurel for Bardeen, Cooper and Schrieffer.

If this view of the birth of tunneling in superconductors and of the Josephson effects seems a bit romantic, it is because I, after a decade of rummaging among the contents of the cornucopia, still find the whole affair rather magical. The task which Dr Solymar has set himself in writing this book is to present the results of the first decade or so of research on superconductive tunneling, magic included, in a form accessible to final year undergraduates and postgraduates in physics and electronic engineering, and to specialists in other fields who wish to learn what all the fuss has been about and perhaps to contribute to

the continuing development of this field. This is no easy task. Much of the fundamental theoretical foundation is highly sophisticated. Although, after a decade of intensive work, it can fairly be argued that there remain few if any major mysteries in the field, contributions to knowledge of the basic phenomena continue to appear, and reports of advances in technologically relevant areas, especially of the Josephson effects, are proliferating beyond the ability of mortal man to keep track of, much less read and understand. Solymar's solution to the problem is to exploit a feature which superconductive tunneling shares with certain other physical systems, like the hydrogen atom: although one's study of the system can be carried to almost any level of complexity and sophistication, there exist levels at which real understanding, together with an appreciation for the beauty and the magic, can be conveyed to almost any student with a modicum of background.

He avoids the details of the microscopic theory, concentrates on phenomenological descriptions and models, and succeeds in presenting a comprehensive and understandable picture of the whole field in less than four hundred pages. It is all there: normal electron tunneling, Josephson tunneling, special effects, diagnostic and device applications, device fabrication, fluctuation phenomena, even a fascinating statistical note on the development of the field as measured by publications—number, journal distribution, country of national origin, and so on. It is a kind of Michelin green guide to the field. And for the reader who wants more than a two-paragraph or two-page introduction to the history of a particular château, there is a complete reference list (nearly 10^3 entries) to which he can go to learn everything that's known (or conjectured) on the subject.

As I understand it to be a reviewer's duty to carp, I am compelled to say that the relative emphasis on topics is sometimes not to my taste, that the urge to comprehensiveness has sometimes led the author to rather tedious listings of "X did Y experiment and measured Z", and that the proof reading leaves something to be desired (for example R. A. Ferrell's name consistently misspelled, the tin gap frequency reported at half its actual value (page 119), Figs 11.3 and 11.4 interchanged). On the whole, however, I think this book provides a remarkably good introduction to the field, one which I would (and will) recommend to any of my students or colleagues who wish to understand what superconductive tunneling is all about. I wish I had written it.

D. N. LANGENBERG

Einstein

ALBERT EINSTEIN
Philosopher-Scientist
P. A. Schilpp, editor

Such a modest man and yet an intellectual giant. Here is a book which Einstein was proud of, and gave to his friends.

"This book is so complete that it is likely to remain the standard work of the great philosopher in the light of contemporary knowledge."

(Journal of the Franklin Institute)

"The publication of this book is an event of major importance for philosophy and science. The most valuable contribution is Einstein's (one and only) autobiography... a natural and fascinating description of the growth of his ideas."

Sir Edmund Whittaker (Scientific American)

Contents:

- Einstein's Autobiography
- Critical analysis and evaluation by 25 scholars and scientists—among them Bohr, Born, de Broglie, von Laue and Pauli
- Einstein's reply to his critics
- Comprehensive bibliography
- Third edition, 1969 xviii+781 pages

For Discriminating Collectors

A limited number of leatherbound, deluxe, numbered, uncut, boxed, and Einstein-autographed first edition (1949) copies are now on sale. Only 760 in print. A truly magnificent and valuable gift for the lover of fine books.

Order with the coupon below:

Open Court Books

Box 599 La Salle, Ill. 61301

Please send postpaid the following Einstein volumes. My payment is enclosed.

- ☐ Clothbound \$15.00
- ☐ Paperbound (2 volumes) 6.90
- ☐ Limited Edition 295.00

Paying the Civil Service Scientist

THE question of scientists' pay is not one for glib editorialising. Within the confines of a thousand words it is simply impossible to give a rational assessment of what should be done to the present simple pay structure for the enormously complex organisation that is the British Civil Service. What one can do is try and see broader issues. The contributions in *Nature* by Dr Leigh (248, 184; 1974) and Drs Gibson and Hawtin (in this issue) deserve careful reading because they clearly set out some of the fundamental questions underlying the present impasse.

In the late 1940s the Priestley Commission established that the pay of civil servants should be removed from the "cockpit of politics". To this end it proposed that parity be maintained with salaries outside the Civil Service and this, despite the inflexibilities of salary scales and increments, worked tolerably well for many years. Scientists were always in a potentially anomalous situation, since although they do not form a large percentage of all civil servants, they do account for more than half of Britain's scientific research manpower when scientists in fringe bodies (whose pay scales are coupled to civil service rates) are included. Far from avoiding pace-setting, which was Priestley's hope, scientific pay rates in the Civil Service cannot but set the pace for all scientists' pay. Up to 1971 the circularity inherent in this system was avoided by establishing broad parities between the scientific categories and their counterparts in the administrative, professional and technical grades. Since then the internal parities have been discarded and external parities sought through so-called 'pay research'. The result of this exercise did not satisfy the Institution of Professional Civil Servants, representing the scientists, and the matter is now with the Pay Board, whose decision is expected within weeks. There is no dispute, however, over the fact that scientists have slipped behind in internal parity during the dispute nor that they have conducted themselves with restraint. It is inconceivable that they should not be well rewarded by the Pay Board or that their forbearance should penalise them.

There are three salient points which need some emphasis: that going off an internal parity has created some nonsensical situations which deserve urgent attention; that the government, in deciding its own scientists' pay, is deciding the status of a profession; and that the role of government in science is worth continued questioning.

Every scientific civil servant can point to anomalies in structure. For instance scientists as they become more senior become more likely to administrate, and to main-

tain a distinction between administrators who have followed different paths to their present position is manifestly absurd. Nor is the anomaly confined to the upper echelons, for many scientists could easily have been classed as technologists and *vice versa*, yet there are now hundreds of pounds between comparable categories.

More important than repairing these frayed edges, though, it is vital that the question of civil servants' pay is seen for much more than that. Like it or not, the Pay Board finds itself evaluating the financial rewards of all scientists and, because of this, affecting recruitment into science as whole and even the decisions that have to be made (as Drs Gibson and Hawtin point out) years before a young person starts work. Thus a decision consciously to differentiate between the pay that comparable arts and science graduates can command would have repercussions for many years to come. There is no visible sign that the government has decided that it wants a long term decline in numbers going into the scientific profession, indeed it has probably given little thought to the matter, but a settlement that leaves dissatisfaction in the scientific ranks will do much more than lead to temporary discontent.

Finally, and the greatest of the issues raised, does the government know what it wants of its own scientists?

It is obviously attractive to have all those scientific brains at one's disposal but are they always used to advantage? It would be unfair to ask for some sort of deal by which Civil Service science is reviewed in exchange for the coming pay award, but it does seem worthwhile to look again at the whole question of the government offering stable long term employment to such a large number of scientists. There is a feeling that the government holds too many scientists in an undemanding 'parking orbit' and industry and the universities should assume many of the piecemeal roles which the government has acquired. A fairly vigorous policy of hiving off over the next ten years, benevolently supervised by the government, may be no bad thing. And maybe to go with a reduced establishment, greater flexibility could go into pay negotiations. Collective bargaining removes much of the personal involvement that those with highly individual skill should have with their management. It would be good to see a greater devolution of negotiation on to management.

100 years ago

A SUPPLEMENTARY credit of 4,000*l.* has been voted by the Versailles National Assembly for paying a part of the expenses incurred by the observation of the Transit of Venus. Six members belonging to the ultra-clerical party have given a negative vote on a division. It is said they are not believers in the Copernican theory, and have no faith in the astronomical observations.

From *Nature*, 9, 452, April 9, 1874.

Seasonal rainfall forecasting in West Africa

Dr Derek Winstanley, now at the Ecological Systems Research Division, Environment Canada, Ottawa K1A 0H3, emphasises that seasonal rainfall forecasting is vital if early warnings are to be obtained of food shortages.

Fig. 1. Mean percentage of normal (1931-60) June rainfall at 59 stations between 10° and 20°N, from the Atlantic coast eastwards to Chad, plotted against the mean percentage of normal June-September rainfall for the 20 years 1953-72. The regression line has been derived by the least-squares method. Data sources are refs 5 and 6

Food production and the maintenance of the ecological balance in the semi-arid zone to the south of the Sahara depend on the rains which fall from June to September. For the past six years the rains have failed¹. Last year 3.5 million head of cattle worth £180 million perished, there was a grain shortage of 1 million tons and some 6 million people were placed on the brink of starvation. In order to avert disaster on an unprecedented scale in 1974, an increase in the already massive amount of international aid is essential. Clearly, successful seasonal rainfall forecasting could lead to an early assessment of food shortages.

I have taken 59 stations between 10° and 20°N, from the Atlantic coast to Chad, and have calculated the mean percentage of normal (1931-60) rainfall for June and for the wet season June-September each year during the period 1953-72. The mean June rainfall for the 59 stations is 124 mm and the mean amount for June-September is 636 mm, 88% of the mean annual total.

Figure 1 shows a highly significant correlation ($r = +0.63$) between June rainfall and the seasonal total. When June rainfall is below normal the total seasonal rainfall is also below normal.

There is clearly a strong tendency for anomalous rainfall patterns to persist throughout the wet season. This suggests an equally strong persistence of the large scale atmospheric circulation systems which control rainfall. The year 1968 was rather anomalous in that June rainfall was 17% above normal but the seasonal total was 23% below normal. This

was the first year of widespread rainfall deficiencies and it is possible that there was a rapid switchover of circulation types in about July of that year. Figure 1 shows that the subsequent dry years fit into the pattern.

The rainfall deficiency in this zone increases with latitude¹: at 18°N there has been a cumulative rainfall deficiency of 250-300% of normal since 1968, whereas at 10°N there has been only a small decrease in rainfall. I have previously suggested that the cause of this decrease in rainfall is a decrease in the northward extent and intensity of the ascending branch of the Hadley cell, concomitant with a weakening of the global atmospheric circulation¹⁻³. Taking the annual number of days of the westerly weather type over the British Isles as an indicator of the strength of the global atmospheric circulation⁴, it is apparent that for the past few years the global circulation has been weaker than at any time for about a century. The drought to the south of the Sahara thus represents an extreme situation but I have suggested that such droughts may become more frequent in the next 60 years³.

It is doubtful whether any nation can cope with a cumulative rainfall deficiency of 300% over 6 years. But the very fact that there are such large scale atmospheric controls on rainfall could provide a rational basis for integrated long term development. What must be determined are the maximum cumulative rainfall deficiencies that can be expected. It must then be decided what level of rainfall deficiencies can be tolerated, if the countries are to maintain some degree of self-support, either nationally or through some political or economic union. Development should then be encouraged in the more favourable areas, even though good rains may extend farther north in some years.

In 1973 world cereal stocks were reported to be at the lowest level for 20 years. Significantly, it was adverse weather in the Soviet Union in 1972 which led to the purchase of huge amounts of American grain; this, probably more than any other single factor, led to the depletion of world grain stocks and the escalation of world food prices. With depleted world cereal stocks it is not easy to guarantee supplies for major disaster relief programmes. Assuming that supplies are available on the international market, the high prices cripple the economies of the drought and flood-affected developing countries; in the case of India, the high cost of food imports has also necessitated the curtailment of the family planning programme.

The main development constraints in this zone are surely climatological, but the task of development seems to be beyond the individual capabilities of the governments. In any future development plans there are three points to be taken into consideration. First, large scale atmospheric circulations exert a unifying influence right across this zone, such that there will again be years when the rains fail over some 5 million square kilometres. Second, the atmospheric controls on rainfall are such that percentage deficiencies, and surpluses, will always increase with latitude. Third, climatic fluctuations in this zone are closely related to climatic fluctuations in other parts of the world, so that in some years there are likely to be synchronous food shortages in different regions which could affect world food stocks.

international news

Steel on steel for British rail

John Wilson

BRITISH RAIL (BR) will use steel wheels on steel rails to drive and support intercity passenger trains of the 1980s, travelling at speeds up to 300 km h^{-1} (188 mph). Mr Mike Newman, in charge of BR's Advanced Passenger Train (APT) project, says that no existing linear motor can compete with present conventional electric units in efficiency and believes that the development of a magnetic suspension system with its costly new track is unnecessary for this sort of speed. His opinion conflicts with that of the Commission of the European Communities which recently invited manufacturers of high-power linear motors to Brussels to discuss cooperation in the development of just such a magnetically suspended, linear-motor driven system.

An experimental APT has already started a three year development programme by travelling at 200 km h^{-1} (125 mph) on a test track near the Derby works. This experimental train consists of a power car at each end separated by two trailer cars only, but commercial versions should propel about seven trailer cars. The whole articulated unit is highly streamlined and has a very low cross sectional area, roughly that of Concorde. The final versions will be built as very light semi-monocoque stress skin structures, a technique borrowed from the aircraft industry, and indeed the whole unit resembles an aircraft rather than a train in the design of the interior equipment and accessory systems.

The experimental APT is powered by conventional gas turbines, for the success of the British APT lies not in any revolutionary power plant but in its novel suspension system. Dynamicists at the Railway Technical Centre in Derby were the first to work out the complex mathematics of the ordinary railway wheelset (two flanged wheels rigidly attached to a live axle). They discovered that by altering the cone angles and tyre profiles of the wheels they could make the set roll with a minimum of oscillation. This allows the APT to be run at speeds of up to 250 km h^{-1} (155 mph) even on existing track and to negotiate main line curves

British Rail's APT: running on the same lines into the eighties

50% faster than conventional trains.

Greater speeds than these are possible with APT variants using more powerful engines, but considerable modification of the track is necessary. Mr Newman notes, however, that any improvement made in the track for the benefit of the APT would also benefit normal services. This is in contrast to other methods of high-speed travel where the new track is for the exclusive use of the new vehicle.

The keynote for BR's plans for the new train is the utilisation of existing assets. The brakes, for example provide double the usual performance expected for a normal train—and this in a vehicle of less than half the normal weight. For this reason the early APT's due to begin a trial service on the (London to Glasgow) West Coast main line in 1978 should be compatible with existing signalling equipment. Mr. Newman points out that by improving the track alone electric trains already in service could almost match the performance of the APTs. On a route such as London to Glasgow, which an APT with a speed of 250 km h^{-1} (155 mph) could travel in 3 hours 47 min, a conventional train could take as little as 3 hours 50 min—if all the necessary track improvements were made. Although it is worth noting that the APT could then chop another 37 minutes off this new improved route, the point is that these comprehensive track improvements would cost up to ten times more than an APT system.

The APT is an attempt to stretch an essentially Victorian railway system using 1960s technology. Any successor to the APT will have to be a completely new system. This is because the introduction of APTs is expected not only to compete more effectively with motor-

ways and airlines but also to generate considerable trade itself—to the point, in fact, where the system becomes saturated. It is this saturation, expected about the 1980's, not the need for higher speed, which will lead to the necessity to construct new track, and it is at this point that systems using linear motors, hovertrains and the rest begin to seem attractive.

Cancer research runs into trouble

Colin Norman, Washington

A COMMITTEE of biomedical scientists has delivered a stinging attack on a prominent and highly controversial cancer research programme supported by the US National Cancer Institute. The committee's criticisms and complaints cut deep into the philosophy underlying much of the loudly proclaimed federal war on cancer. Because they raise the basic objection that cancer research shouldn't be targeted and managed like a NASA-style operation to land men on the moon.

The research programme in question, the Virus-Cancer Program (which used to be called the Special Virus Cancer Program) is the epitome of the highly managed, centrally directed approach to cancer research. It now disburses more than 40 million dollars a year, entirely in contracts, to universities and industry for studies on cancer viruses and for the development of resources to support such research.

Ever since it was started ten years ago, with the specific approval of Congress, the Virus-Cancer Program (VCP) has been attacked for a variety of sins, chief of which is that it has been directed by a few people who have

amassed considerable power for themselves and that it has taken money away from potentially more productive research efforts.

In response to such complaints, the National Cancer Advisory Board, the body which oversees the work of the National Cancer Institute, set up a committee last year under the chairmanship of Dr Norton Zinder of Rockefeller University to take a look at how the programme is working. The committee turned in its final report to a board meeting in mid March and it said that virtually all the criticisms that have been raised against the VCP have some credence.

The committee's most basic objection is that "ignorance of the mechanism involved in the cancer process is so profound that it is difficult to be certain where to begin, much less to organize a focused attack". In other words, the basic knowledge just isn't available to begin a concentrated, highly directed research programme on cancer viruses, and the committee reckons that the best way to get the basic knowledge is to support a more broadly based research programme in the universities.

When congress passed the National Cancer Act two years ago, which set in train large increases in funding for cancer research, the implicit suggestion was that by shovelling more money into research and planning the effort with operations research techniques, answers would eventually emerge. A central feature of the act was, in fact, that a national cancer programme plan would be drawn up to provide a framework for the whole operation.

Since the committee's chief objection challenges the philosophy behind the Cancer Act, the report has had a surprisingly warm reception from the people who are in charge of the war on cancer. Dr Frank Rauscher jun., the director of the National Cancer Institute, said in an interview, for example, that the committee produced "a damn good report" and that the Cancer Institute is in fact in the process of righting most of the ills which it spotlights.

But the official enthusiasm for the report is not shared by the scientists who are operating the VCP. They sent a memorandum to the National Cancer Advisory Board in January charging that the committee's suggested improvements in the programme are "based on total destruction of the programme, and not on constructive modifications which could readily be implemented." They also charge, in private discussions, that the committee's criticisms were directed at a few individuals in the programme, on a rather personal basis.

In fact, the committee first presented its report to the National Cancer Advisory Board at a meeting last

November, but the board said that it was going to be so negative it ought to make its criticisms more specific and name names. But the report presented last month was unchanged from the earlier version. Asked why it had not been made more specific Dr Zinder said last week that it was meant to be an overview of the programme and he did not think it proper to single out individuals. He added that the members of the committee are willing to stand behind everything they said.

As for the committee's objections to the programme itself, they centre chiefly on the fact that the VCP is managed by a small group of scientists who have considerable power over the selection of contracts and the report suggests that the process by which contracts are reviewed is not very rigorous. In particular, the committee recommends that bidding for contracts should be more competitive, and that they should be reviewed by panels of scientists drawn from outside the National Cancer Institute.

Although it doesn't say it specifically, implicit in the committee's recommendations is that much of the money now distributed by the VCP through contracts should be made available to the academic community to support individual grants for projects suggested by researchers themselves and not by a handful of managers within the National Cancer Institute.

Zinder said last week that all the committee was trying to do is to "open the programme up to the academic community" by getting more outside people on the review committees and making more money available for investigator-initiated research projects.

The VCP scientists' memorandum to the board says, however, that the programme is not such a closed shop as the committee implies. The contracts support more than 2,000 individuals, including 600 professional scientists and 230 postgraduate and postdoctoral students, whose combined output of scientific papers in 1972 totalled 1,183. Moreover, between July 1971 and January 1974, the VCP received 149 unsolicited proposals for research projects and funded 22 of them, so there is a place for investigator-initiated research in the programme.

Be that as it may, several changes are being made within the National Cancer Institute as a whole and the VCP in particular which meet many of the objections raised by the review committee. For a start, the review process for contracts is being changed to allow greater participation by scientists from outside the National Cancer Institute. An overall advisory committee is being established for the VCP, which will consist entirely of outside scientists and which will advise the director of

the programme and the contract managers on the overall direction of the effort. And the committees which review individual contracts are being reconstituted so that outside scientists will be in the majority.

But the most far reaching change is that the National Cancer Institute is exploring a new funding mechanism which Rauscher calls programme grants. These will be broad based grants to university scientists which will not be encumbered by the controls and specific objectives that are attached to contracts. They will be used to support research designed to fill specific knowledge gaps. The idea is that programme grants would be peer reviewed by multidisciplinary study groups and they would run for perhaps three years.

Lamb's unit to the slaughter?

Allan Piper

THE existence of one of the two climatic research establishments in the western world, the Climatic Research Unit (CRU) at the University of East Anglia, is threatened by lack of financial support, at a time when the importance of climatic research is becoming increasingly clear.

Variations of climate cannot be prevented but they can be predicted with increasing reliability. Advance knowledge of an impending catastrophe—a drought, a flood, a severe winter—allows for careful planning which may often save lives and money. The CRU has been in existence for only two years and its director, Professor Hubert Lamb, says that the prospects for climatic research are excellent: "the plums are ripe for the picking, we only need someone to provide a stepladder".

The climatologists at the CRU are working towards the development of an increased understanding of the mechanisms and causes of climatic fluctuations. They have collected extensive data on weather and climatic behaviour going back to about 1200 AD and present day climatic developments are monitored on a global scale, often using observations from satellites. The knowledge acquired is used to supplement the present statistical techniques of ascertaining likely climatic trends and it is hoped that this will lead to increasingly reliable predictions.

Ever since the CRU was established in January 1972, it has had to operate under restrictive financial conditions. Initial grants came from the Nuffield Foundation, Shell International Petroleum, British Petroleum (BP), the Electricity Council and the Central Electricity Generating Board. These grants amount to less than £60,000 spread over five years and although

Professor Lamb considers them to be "very generous indeed", it is apparent that, compared with other research establishments, the unit is working on a sadly inadequate budget. Furthermore, an initially bad situation has been worsened by the effects of inflation, which eventually forced the withdrawal of the support from BP, although the other contributing bodies have been able to provide appropriate incremental adjustments. Now it is clear that by the end of 1975 the funds of the unit will almost certainly be largely exhausted. Even if the present grants are renewed, Professor Lamb can only remain cautiously optimistic about the likelihood of obtaining support from other organisations.

This is rather disappointing because there is a good case for increased financial investment in climatic research. Modern commercial and industrial techniques are geared to utilising to the limit any available resource, such as water, livestock or crops, and production methods are increasingly arranged to maximise profits. It is always likely that such finely adjusted projects will be vulnerable to any shift in climatic behaviour. Established patterns of production may become severely disrupted, often with disastrous consequences. A continuing decline in

rainfall can ruin not only intensive agricultural projects, but also sophisticated technological schemes such as hydroelectric power plants, or industrial processes which may be sensitive to such factors as atmospheric humidity. Results of recent research to assess differences in agricultural yield between a wet and a dry summer in New Zealand indicate that £2 million a year may be lost just on cattle in one small region alone. Investment in climatic research could save much of this: foreknowledge of climatic trends can facilitate advanced administrative planning, allowing otherwise catastrophic situations to be mitigated, if not avoided, by careful preparations of all necessary assistance.

The results which have so far been produced by the CRU, covering the past two years, are encouraging although not entirely accurate. According to Professor Lamb, however, the inaccuracies illustrate the problems of operating with restricted financial resources. Retrospective reappraisal of the data used reveals that the correct information had, in fact, been assimilated but it was misinterpreted and wrongly collated.

The errors arose chiefly because the unit is drastically understaffed, says Professor Lamb, and the consequent

pressures have not allowed for the assimilated data to be used to its best effect. As a result, the preliminary series of seasonal forecasts has had to be discontinued. There is both the room and the necessity for research workers at all levels of experience from graduate students upwards, and there has been no shortage of suitably qualified applicants; unfortunately the present financial stringency precludes any expansion. A ideally qualified, highly regarded applicant was recently refused a senior research post because of the lack of necessary funds.

Professor Lamb's disappointment is hardly surprising. With the unit left with a guaranteed existence of less than two years, he is not finding it easy to negotiate new sources of support although BP are considering the provision of renewed assistance. It is difficult to understand the reluctance of agricultural and industrial organisations—let alone governments—to grant the required funds, particularly in view of the enquiries already received by the CRU. These include requests from an industrial concern for information about the probability of severe winters occurring simultaneously in Europe, the USA, and Japan, and requests for forecasts from farming organisations in Norfolk, France and even Zambia. But Professor Lamb feels, not unreasonably it seems, that it is the international agencies which should provide substantial support for research which is "vital to the needs of mankind at the present time".

The position of the Natural Environment Research Council (NERC) is also interesting. It is the policy of the council to provide funds only for specified research projects; it will not allocate finances to assist in establishing a research group. For this reason the NERC did not provide support when the CRU was founded back in 1972. Today the NERC provides support for a research student at CRU but will not help to establish any new research projects. This policy contrasts markedly with that of the Medical Research Council (MRC) which will provide 'programme grants' to support "the particular situation in which a university has formally decided to develop a specific plan of study, and the Council agrees in the national interest to assist that development in that particular university."

It would be a pity if the existence of CRU were to be placed in jeopardy after such a short existence, at a time when the potentialities of the research work are about to be realised. The research staff have begun to establish liaisons all over the world, and it would be a great disservice to climatic research if these relationships were allowed to collapse.

US nerve gas plan under fire

A BRITISH expert on chemical and biological weapons has blasted the US Army's plans to develop a new generation of nerve gas weapons on the grounds that they will kill attempts to negotiate an international treaty banning production and stockpiling of chemical weapons. Julian Perry Robinson, a member of the Science Policy Research Unit at Sussex University who has been conducting a study of chemical and biological warfare for the Stockholm International Peace Research Institute, delivered his attack on the army's plans at a symposium organised by the American Chemical Society on April 1.

In September last year, the US Army announced that it is planning to produce new, "safe" nerve gas weapons at the Pine Bluff arsenal in Arkansas. The idea behind the weapons, which are called binaries, is that they will consist of two chemical components neither of which is lethal by itself, but which form a highly potent nerve agent when they are mixed together. The two chemicals would be loaded into separate compartments of a shell and allowed to mix only when the shell is safely on its way to the target.

The army is claiming that binary weapons have the advantage that they are safe to store, and transport, and it is planning to replace the immense

stockpiles of conventional nerve agents now stored in bases throughout the United States and abroad with binaries. These stockpiles have generated considerable public alarm, and opposition to the entire chemical weapons programme in the United States. The army is therefore hoping that its new safe weapons will be more acceptable.

Robinson points out, however, that a programme involving the production of binary weapons and the destruction of stockpiles of conventional nerve agents will cost American taxpayers as much as 2,000 million dollars.

But a more basic criticism of the programme is that if the United States now launches a massive new nerve gas programme, it will completely destroy the credibility of US intentions to negotiate seriously for international chemical weapons control. Talks have been taking place in Geneva for several years on a possible treaty banning use and stockpiling of such weapons, and although the United States position has not been exactly enthusiastic for such a treaty, at least it has shown willing to talk. Robinson argues, however, that "a decision to go ahead with binaries would almost certainly mean an end to the disarmament negotiations, and with them a prospect for improving US security to a far greater extent than binaries ever could".

Oil prices hamper oceanography

FOR most users of oil the recent price rises have simply meant paying more for the commodity and finding ways of living with the greater expense. For some, particularly those receiving fixed sums of money from the government, paying more is not possible without going bankrupt. In scientific research the worst affected are the oceanographers.

In Britain the Natural Environment Research Council (NERC) operates many of the research ships for universities and its laboratories. Largest of these are the *Bransfield*, *Discovery*, *Shackleton* and *Challenger*, although there are many smaller vessels some of which are the direct responsibility of individual universities. An official of the NERC pointed out that there would be an increase of "several hundred thousand pounds" in the 1974 fuel bill for these ships, this in a total budget for the operation of research vessels of only £1.5 million. As yet the NERC has not been able to extract any promises of extra money from the Treasury, so although marine operations are for the present carrying on as usual, within a few months there is a serious danger that cruises will have to be curtailed or cancelled.

One oceanographer expressed concern that the short term problems with oil prices should not affect long term decisions on building new oceanographic vessels. "It is clear that large scale capital expenditures are very vulnerable at times like these", he said, "but we cannot indefinitely postpone the renewal, let alone the expansion, of our oceanographic fleet". At present there are no new ships planned but there seems to be a general feeling both that some vessels cannot last much longer and that oceanography actually needs more ships to satisfy the demands of research workers. It looks, however, as if survival at the present level of activity is going to be the most that the NERC can aim for in the next year or two.

Soviet reactor accident: official

from our Soviet Correspondent

REPORTS of a serious accident to the BN-350 fast breeder reactor at Shevchenko on the Caspian Sea, although strenuously denied by official Soviet resources, do seem to have some foundation in fact, although the failures involved belong to the field of conventional, rather than nuclear, engineering.

According to Dr N. V. Krasnoyarov, interviewed when in London for an international conference on fast reactor power stations, three out of the six

generators of the Shevchenko station have, in fact, been taken out of service following faults in the interface of the secondary (sodium) and tertiary (water) circuits. In one case, the leakage of water into the sodium of the second circuit was observed at a very early stage and the generator was immediately closed down; in the other two cases, the water, reacting on the hot sodium with consequent liberation of hydrogen, caused a pressure buildup which resulted in the rupture of what Dr Krasnoyarov called "special safety membranes" (presumably bursting disks); the products of the reaction were conveyed to a special dump tank and the generators concerned were closed down.

All three faulty generators are now undergoing repair; in the meantime, the other three are being operated at below nominal capacity, giving a total output at the station of some 30% of its rated power. The deficit of power required for electricity generation and desalination is at present being supplied by the conventional oil-fired generators which the BN-350 was designed to replace but which were retained as a peak-demand backup. The primary (radioactive) sodium circuits were in no way involved.

The rumours that more serious damage had been detected by United States surveillance satellites seem to have grown by a snowball effect, from 'If

there had been a serious accident, the satellites would have detected it' to 'The satellites have detected a serious accident', and the July dating seems to have crept in by confusion with the date of commissioning of the station. The growth of the story was in no way quenched by the tone of the official denials. According to the Novosti agency, Academician Andranik Petrosyants, Chairman of the State Committee for Atomic Energy of the Soviet Union "emphatically denied" that anything untoward had occurred. Instead of the reasonable explanation offered by Dr Krasnoyarov, Academician Petrosyants simply maintained that "all this information does not correspond to reality" and that the report "is an invention and obviously pursues some other aims", being directed against Franco-Soviet cooperation in fast breeder reactors. "It is evidently of benefit to some people to try to do damage to that cooperation and set public opinion against that cooperation by inventing 'explosions'."

The tone of the denial seems inspired by considerations of prestige, rather than a desire to impart information. Perhaps if Academician Petrosyants had, in the name of the "cooperation" he advocates, been a little more forthcoming about what are after all relatively minor faults, his denial of a major disaster might have been found more credible.

Better deal for polytechnics

THE 30 polytechnics in Britain are to get a better deal from the Science Research Council (SRC) as far as postgraduate studentships are concerned but the criteria governing the award of research grants will still favour university-type research. This move follows the report of the SRC's Polytechnics Working Group which has been considering the relationship between the SRC and the polytechnics since 1972.

The SRC is to put its new plans into operation through a new Committee on Postgraduate Training in the Polytechnics, which has been set up for a three-year period under the watchful eye of Dr A. H. Chilver, Vice-Chancellor of the Cranfield Institute of Technology. The Committee will be empowered to award advanced course studentships (usually lasting one year and aimed at the taught postgraduate course which the polytechnics have been encouraged to set up).

As to the award of research studentships, usually held for three years, the new committee will only advise other parts of the SRC "on any special factors to be taken into account in the award of research studentships to polytechnics". The SRC is keen that this should result in the channelling of more of

the so-called CASE awards (Cooperative Awards in Science and Engineering) to polytechnics, thus giving a fillip to the cooperation between polytechnics and industry which the Department of Education and Science has always been keen on. At the end of 1972 students in polytechnics held 1.7% (104) of all SRC research studentships and 2.9% (45) of its advanced course studentships.

The volume of research in polytechnics is bound to increase in the next few years because by 1981 the government plans that there should be 180,000 undergraduate and postgraduate students in polytechnics on full-time or sandwich courses, compared with 68,000 in 1972. Clearly there will be a big demand for whatever the SRC has on offer.

Dr J. S. Bosworth, Director of Newcastle-upon-Tyne Polytechnic, said last week that the SRC's plans are certainly a good step in the right direction. He pointed out, however, that it is particularly important for polytechnics to get together with other interested parties and define just what research they are to do. In this way, he said, it should be possible to arrange a framework in which polytechnic-type research could be sensibly planned and carried out.

Lead in the environment

A RECENT report of rising levels of lead in the blood of people living near a large British motorway interchange has highlighted the problem of lead pollution through exhaust emission. Lead can enter the environment in many ways. Food is generally considered to be the main source of lead intake; it has been estimated that each person takes in about 200–250 micrograms of lead in food daily. Lead is also released during lead smelting and other industrial processes but these are now subject to strict controls and although there is still pollution this affects only small areas.

In 1972, about 90,000 tonnes of lead were added to petrol in the United Kingdom alone. Plans to reduce the level of lead in petrol to 0.45 grams per litre by 1975 have had to be shelved in view of the present oil crisis as producing high octane grades of petrol without the use of lead additives needs much more crude oil. At present the permitted maximum in the United Kingdom is 0.64 grams per litre.

The survey of blood lead levels of adults and children living around the Gravelly Hill interchange, 'Spaghetti Junction', was carried out by Birmingham City Council. Before the interchange opened in 1972 lead levels in residents' blood were on average 12.2 micrograms per 100 millilitres and last October had risen to an average of 16.6 micrograms. This January they showed a rise to an average level of 21.0 micrograms by the hospital analysis and 26.3 according to the Birmingham City Analyst. These discrepancies highlight one of the main problems in lead toxicology; the variability inherent in the methods used to measure blood lead levels.

The inference that is being drawn from the Birmingham report is that lead from traffic exhaust fumes is the cause of this rise in blood levels. The Birmingham Health Committee have expressed concern and are drawing the government's attention to the report. Although the average levels do not yet approach the accepted toxicity levels and are not above the upper limits for normality, a great deal of concern has been expressed over the past few years about the long term effects of exposure to subtoxic levels of lead especially in children. Also, there are bound to be individual higher than average levels.

The maximum acceptable level of lead in the blood of adult male workers exposed to lead for an eight hour day is considered to be 80 micrograms per 100 millilitres. For children the general consensus of opinion takes 36–40 micrograms as the upper limits of nor-

malinity and considers 60 micrograms as cause for concern even though the child may not be showing any symptoms.

The whole question of the relation between the amount of lead in the atmosphere and its absorption into the body and link with blood lead levels is under intensive study at present. A study in 1972 by the Medical Research Council's Air Pollution Unit found that atmospheric levels of lead had risen in a busy London street from an average of 3.2 micrograms per cubic metre of air to 5.4 micrograms. A small survey of London taxi drivers during this time compared the blood lead levels of daytime with night-time drivers. Although

Spaghetti Junction: children at risk?

the daytime drivers were subjected to a higher level of exhaust pollution (monitored by the carbon monoxide effect on the blood) their blood lead levels were similar.

Much work on the size and aerodynamic properties of the lead particles given out in exhaust fumes is in progress. It has been estimated that about one-quarter of the lead content of petrol remains in the engine and the rest is given out in the exhaust as fine particles of lead compounds. Of this about half is thought to be deposited within a few hundred feet of the road but the finest particles may be carried considerable distances in the air. The fate of these particles in the lungs and how much is finally absorbed is also under study. The Atomic Energy Research Establishment at Harwell have just embarked on a study of the intake of radiolabelled lead from exhaust fumes to try and throw light on this problem. Earlier work on artificial aerosol lead intake indicated an uptake of about 40–50%, and more recent

work in other laboratories suggests that about 15–20% of atmospheric lead is absorbed. Some workers, however, think that this figure is too low.

At present, there are many surveys measuring atmospheric and blood levels but it is often difficult to correlate the results of such different surveys. In a recent report, the Central Unit on Environmental Pollution drew attention to the difficulty of correlating results from different surveys. The report names lead as one of six pollutants which need monitoring on a wider scale than before. They recommend that a network of 20 sites be established in various areas to monitor trace elements by a standard technique. At present, a survey of traffic fume pollution is underway in five major British cities, coordinated by the government's Warren Spring Laboratory.

Additionally, the Worshipful Company of Pewterers celebrated its 500th anniversary by setting up a trust fund to provide an income of £10,000 a year for a research group at the Institute of Neurology, enquiring into the effects of heavy metals on the central nervous system. The first Pewterers Fellow, Dr Jeremy Barlow, has pointed out that, for the time being, the group doesn't quite know what it's looking for, but that there are certain facts, like the increased incidence of mental retardation in children in recent years, and about the amount of lead in the environment, which may or may not be related to each other.

The situation is further complicated by the fact that some individuals have a greater tolerance of lead in the body than others; one man may have taken in lead to the extent that his blood contains 1,000 micrograms per millilitre, and appear to be no worse off for the experience, whereas another individual may exhibit the clinical symptoms of lead poisoning at levels which are accepted as relatively safe. What's more, the symptoms are easily confused with the general symptoms of what is known as 'modern living' — gut pains, insomnia, loss of appetite, and headaches, so that it's difficult to say that lead is specifically responsible whenever these symptoms occur.

Clearly a great deal of research has yet to be done before it is possible to say whether or not atmospheric pollution from car exhaust fumes is in any way responsible for higher levels of lead in the body, and that life, or health is endangered by the motor car. If we really want to be on the safe side in the meantime, it's possible to cut the lead content of petrol by producing high octane grades at great expense, or to stop using high-compression engines, which would mean that an awful lot of nice new cars would be made obsolete, at a stroke.

correspondence

Prices of scientific journals

SIR,—The risk of being misquoted from telephonic communications (me to *Times Higher Educational Supplement*, October 26, 1973) increase when the misquotation is quoted, for I am the Alec Henderson who figures in John Hall's article (*Nature*, February 15). One original misquotation was that the well known *IEEE Transactions* becomes the mythical *Transactions of the American Association of Electrical and Electronic Engineers*: but the desolating fact is that *IEEE Trans.*, having already gone up from £252 to £321 this year, has now gone up again to £411—a rise of 63% in a year. On the other hand, it is fair to point out that the quoted increase in price in *Current Contents: Life Sciences* applied only if one took a new and optional indexing service.

The rate of rise in journal prices is alarming. That of books has hitherto been somewhat less but some alarming trends are evident, particularly in marking up of in-print books in publishers' stocks. Recent correspondence with the American publisher of a work on polymerisation explained that the rise in the United Kingdom price of a book of 416 pages from around £16 to £24 was due to floating exchange rates, air-freight charges, warehousing and distribution costs and paper costs—all in the case of a book first published in 1972, not reprinted and listed at the original price in the publisher's catalogue dated 1973–74.

University library budgets in the United Kingdom as a whole were not keeping up with the combined effects of rising prices, diversification within universities and proliferation of literature even before Mr Barber's cuts in public spending. To these cuts, particularly to that in supplementation for price increases, they are particularly vulnerable because of the large proportion of their expenditure which goes on books and journals and subacademic staff (supplementation of academic salaries being safeguarded): they must therefore receive generous treatment from their universities if they are not to fall further behind in service to their readers. Librarians thus do not need to be urged by Professor Linnett and his co-signatories to "exercise the greatest reticence on subscriptions to new journals"; they already have to do so,

against the insistence of their scientists (and others) that exception must be made for the latest expensive journal which is just their thing.

If scientists can reduce the volume and cost of publication, whether by refraining from publishing or by compression, they will themselves reap the benefit of the greater accessibility of what is published since their libraries will be able to afford more of the available literature. If Mr Maxwell's plans for *Tetrahedron* will reduce by 80% its price (which I do not suggest is excessive) as well as its bulk, Bubb, Humphreys, Anderson and their fellow librarians will be glad to join with Finniston, Hartnett, Kurti, Thompson and their fellow scientists in praising his "imaginative leadership".

ALEX. ANDERSON

Heriot-Watt University Library,
40 High Street,
Edinburgh EH1 1TQ

SIR,—The best way through the scientific prices jungle (*Nature*, 247, 417; 1974) is for scientists to give wholehearted support to librarians in their efforts to establish objective criteria of usefulness. It is possible to tell how frequently a title is cited in published papers (especially since the "Journal ranking package" has become available from the Institute for Scientific Information); it is possible to tell how often the title is photocopied, how often the title is borrowed on inter-library loan and how often it is being consulted in the library, if each volume and part has a consultation slip. These may not be very good measures of usefulness but they are much better than no measures at all. All that is lacking is a firm decision on the part of the scientific community that:

- No journal should be bought until the cost of borrowing it from the British Lending Library exceeds the cost of buying and storing it on site.
- No journal held on site should be maintained unless objective evidence can be produced that it is being used.

I have little doubt that this policy, if strongly backed, would be a major factor both in improving the quality of science journals and in controlling the prices jungle, to the benefit of library users and librarians alike.

Government scientists' pay

SIR,—It is now widely known that government scientists have been in dispute with the Civil Service Department for over three years because the department has been unwilling to agree on any reasonable criteria for determining the level of scientists' pay. As a result of this long and bitter dispute, government scientists have seen their pay fall, relative to colleagues with whom previously they enjoyed parity, by 20% and in some cases by even more. Since the government is the major employer of scientists in the United Kingdom, this decline in the pay of government scientists has led to the whole of the science area becoming a depressed industry.

What does not seem to be so widely appreciated is the likely long term effect. The status and success of the United Kingdom in the world have been founded to a large degree on the inventiveness of its people and their achievements in the field of science and technology. What is true of our history seems to us even more true today. Yet, at this critical time, we find that 6,000 places for scientists in the universities are vacant, that fewer young people are studying science at school and that scientists are leaving their chosen careers at an alarming rate to take up other occupations.

Since a decision to adopt a scientific career is often taken at the age of 15, in effect it takes six years to train a graduate and nine to train a PhD. Thus the ultimate effect will be to damage the growth of all science-based industries for a decade or more. We believe this is too high a price to pay for an unnecessary dispute.

As responsible members of the scientific community, we look forward to a speedy resolution of the present dispute and to a time when it will again be possible to urge young people to take up science as a socially desirable and reasonably rewarded profession.

Chinese granites and rapid seafloor spreading

THE attention of geologists and geophysicists, for a long time focused on land masses, switched to the oceans in the mid-nineteen sixties when it became clear that the movement of continents could only be understood in terms of processes occurring in ocean basins. Now that there is a fair consensus on submarine geology and geophysics, attention is switching back to continents where there are still some very difficult problems to solve but where the insights of the past ten years can help. Two new papers exemplify the questions that are being asked.

Plate tectonics is a good framework for running the geological clock backwards for the most recent 100 million years, as the magnetic record is well preserved for this period in oceanic crust. Attempts to deduce the disposition of the continents at earlier dates, however, can be less certain because much of the ocean crust formed then has been consumed at island arcs. As with Watergate, the magnetic tape recording is missing, so other sources of evidence must be sought on land. This Jahn does later in this week's *Nature* in using newly determined ages of rocks in south-east China to study a period of exceptionally vigorous seafloor spreading about 100 million years ago. Correlations which he tries to establish within the time of magnetic records may then be extended to earlier times of intensive granitisation when there is no seafloor record.

By a coincidence it is the same area which is the subject of the other paper which originated in the Department of Geology, Nanking University (*Scientia sin.*, 17, 55-72; 1974). Better knowledge of tectonics means better knowledge of mineral deposits. The cycles of tectonic activity in south-east China have led to rich sources of ore, and it is of great importance to know which regions are richest and thus can be most easily exploited.

The Nanking group have dated the distinct tectonic zones of granites that run NE-SW in south-east China. In general the older the rocks the further inland they are. Each zone is about 100 km wide and characteristic ages are 900, 480, 200 and 100 million years, the last being called the Yenshan tectonic zone and forming the coastal belt. The authors indicate the following series of events for each cycle of tectonism: subsidence, sedimentation often with volcanism, orogenic movements, granitisation, regional uplift, subsequent crustal movement and small scale granitisation. They go on to observe "the further development of the Himalayan orogenic zone in our Taiwan province and the presence of island arcs and a submarine trench east of Taiwan indicate that the same tectonic processes have been going on at present".

Analysis of metallogenetic relations and mineralisation capacity of the granite of different zones necessarily produces complex results, but there are some very striking unifying factors. They are best seen in multiple-aged composite granite bodies where several tectonic cycles have left their mark. Ore forming elements such as beryllium, tungsten, tin and niobium are progressively concentrated in the younger bodies. Yenshan rocks contain beryllium, niobium,

tantalum and scandium in workable deposits. The authors conclude that it is the recurrence of granitisation rather than its occurrence on one occasion which leads to significant metallic deposits.

But what are these cyclic tectonic events? It is this question to which Jahn's paper contributes, as it looks at the Yenshan orogeny. Jahn is limited to samples from the offshore islands; these give ages of around 100 million years. Thus the Yenshan orogeny occurs simultaneously with a postulated time of very rapid (up to five times normal) seafloor spreading, established from marine magnetic data. What is more, many others have observed vigorous activity around this period in circum-Pacific regions. Maybe there is a correlation between rapid spreading and intensity of thermal episodes, caused perhaps by an enormous increase in viscous heating as old plate descends into the upper mantle. Jahn is cautious about such a correlation, but the evidence is certainly persuasive.

Some interesting problems are raised by these two papers. If this correlation is correct, is it generally correct to associate all previous Chinese orogenies with times of rapid seafloor spreading (for which it has been already noted there is no magnetic record)? Was rapid spreading a world-wide phenomenon, and how was it caused? Will the next pulse of rapid spreading convert the continental shelf off China into another tectonic belt? These are good questions for bright research students.

Ghost neutrinos emerge from the mathematics

IT is a remarkable fact that even after two generations, the investigation of solutions to Einstein's famous field equations of general relativity is still very much in its infancy. There are indeed very few exact solutions available, and some of those which are have very bizarre properties. One recent solution, published by Davis and Ray of Clemson University in *Physical Review D* (9, 331; 1974) is a distinctive mathematical novelty.

To understand the implications of this new result, first recall that the gravitational field equations of general relativity are a prescription for calculating the curvature of space-time from the mass-energy content of the Universe; that is, the equations relate the geometry of space-time to the physics of matter and energy. Thus for a given distribution of matter say, the geometry of space-time in its vicinity may in principle be deduced. In practice, the equations are prohibitively difficult to solve in all but the simplest cases. One of the earliest solutions, due to Schwarzschild, give the geometry around a spherically symmetric object such as a star. The gravitational bending of light by the Sun testifies to the curved nature of space-time in its vicinity and Schwarzschild's solution gives the correct amount of curvature. Just as the geometry is determined by the material content of space, so in turn the behaviour of mass-energy depends on the geometry. There is clearly a problem of self consistency here.

Among the more elusive of the elementary particles is the neutrino, the particle produced in, among other circumstances, the β decay of a radioactive nucleus. Neutrinos have no mass or charge, but they do carry spin, and are

rather like massless, chargeless electrons. They interact only very weakly with ordinary matter so that most would pass right through the Earth without stopping. Nevertheless, neutrinos cannot be ignored in general relativity, for it is widely believed that they are the most numerous of all particles in the Universe, having emerged in copious quantities out of the 'big bang'. The motion of the neutrinos, which is always at the speed of light, is described by the Dirac equation. A self-consistent solution of the combined Einstein-Dirac equation therefore supplies a possible space-time geometry consistent with a possible current of neutrinos. It is just such a solution which Davis and Ray have found, but one with rather strange properties.

The precise mathematical quantity which describes the curvature of space-time is known as the Ricci tensor $R_{\mu\nu}$, which is a 4×4 array of numbers defined at each point of space-time. Davis and Ray choose a geometry which is restricted partly by having plane symmetry around the x axis and it turns out that for this case only the diagonal components $R_{\mu\mu}$ of the array are nonzero. On the other hand, the physical quantity which curves space-time is the stress-energy, which may also be written as a 4×4 array of numbers at each point. Using the Dirac equation in their selected geometry, Davis and Ray then proceed to calculate this second tensor for the neutrinos. All but two of the components are immediately seen to be zero and of the two that are nonzero neither is along the diagonal. Now in the neutrino case Einstein's field equations simply reduce to the equality of these two tensors (apart from a multiplicative constant including Newton's constant of gravitation, G). Consequently, the two remaining off-diagonal terms of the stress-energy tensor must also be zero, because all the off-diagonal $R_{\mu\nu}$ terms are. So it turns out that the whole stress-energy tensor for the neutrinos in this particular space-time vanishes. Einstein's equations are exactly the same as they would be for empty space. And in fact, these very empty space equations were already solved many years ago by Taub.

At first sight it might seem that Davis and Ray had somehow put the neutrinos in and then taken them out again. This is, however, not so. That the neutrinos are still there is demonstrated by the fact that the neutrino current is explicitly nonzero. In principle it would be possible to detect such a current in a β -decay experiment.

Of course there is no suggestion that the solution described here in any way corresponds to the situation actually found in the real Universe. Nevertheless, it is somewhat surprising to find that the general theory of relativity admits at all the possibility of a current of particles which may produce physical effects, and yet make no additional contribution to the gravitational field. Because of this property Davis and Ray have invented the term 'ghost neutrinos'. It would be interesting to know if ghost particles may exist under a wider range of circumstances.

Amplification of VLF radio signals

VERY low frequency (VLF) radio waves have several interesting properties. In the ionosphere they split into two waves; one is strongly reflected and is of immense importance for long distance communications, the other, the extraordinary or 'whistler' wave, travels through the magnetosphere weakly guided by the Earth's magnetic field.

Whistlers, from which this type of propagation gets its name, were probably first detected on telephone lines in Austria towards the end of the last century, but the first published examples were those observed during the First World War by Barkhausen, a German radio engineer,

as he listened in on allied telephone conversations.

The whistler is a falling tone, the frequencies (f) of which Eckersley found to have travel times which were proportional to $1/\sqrt{f}$. It was not until the early 1950s that Storey, working in Ratcliffe's group at Cambridge, discovered that whistlers were in fact the dispersed radio energy from atmospherics generated in thunder storms. Storey showed theoretically that the VLF electromagnetic energy would propagate along the Earth's magnetic field direction and be received in the opposite hemisphere as a falling tone with the right frequency-time characteristics. The whistlers which were received at Cambridge travelled along paths which carried them to more than 10,000 km from the Earth and showed, for the first time, that at this distance there were an appreciable number of electrons and ions ($\sim 500 \text{ cm}^{-3}$) whereas, formerly it had been considered virtually void.

This discovery triggered off considerable research activity and the number of natural VLF phenomena was multiplied; efforts to explain them lead to a greater understanding of the plasma and energetic particles trapped in the Earth's magnetic field. Many of the generation mechanisms proposed for natural emissions involve growth or amplification of electromagnetic wave by means of resonant interaction with energetic particles. A recent experiment carried out by McPherson, Koons and Dazey of the Aerospace Corporation and by Dowden, Amon and Thomson of the University of Otago (see later in this issue) has revealed that the signal from ground transmitters may also be amplified in the magnetospheric plasma. A signal at 6.8 kHz from a transmitter in Alaska was received in New Zealand at a station which was situated close to the geomagnetically conjugate point. The interesting feature of the experiment was that during the transmission the received signal strength increased, for a short period, from below noise level to a maximum of $35 \mu\text{V m}^{-1}$, before fading again. This maximum value represented a signal 27 dB greater than that calculated theoretically and the authors attribute this to amplification in the magnetosphere.

One of the chief difficulties in this type of experiment is to radiate adequate power at these long wavelengths ($\sim 200 \text{ km}$) and this was neatly overcome by these experimenters by using a monopole held vertical by a balloon at an altitude of between 1 and 1.5 km. Even with this arrangement the total radiated power was only 13 W.

It is interesting to note that McNeill, also in New Zealand, reported (*J. geophys. Res.*, 73, 6860) as early as 1968 evidence of amplification of signals from the Seattle transmitter (NPG) at the rather higher frequency of 18.6 kHz. This effect, which amounted to an amplification of about 10 dB, was noted by McNeill during studies of frequency shifting mechanisms in the magnetosphere.

It is now generally agreed that to receive VLF signals in the conjugate region the energy must be guided by ducts of enhanced ionisation (or perhaps troughs). It seems from work carried out mainly at Stanford that in the absence of such enhancements the wave energy is not guided sufficiently closely to the Earth's magnetic field to produce an appreciable signal in the opposite hemisphere and in some cases the energy may even be reflected or absorbed. McPherson *et al.* and Dowden *et al.* identify the duct in which the propagation probably occurred from whistlers which were observed during the transmission period. All the whistlers observed were shown, by a now well established technique, to have travelled in a single duct and the authors quite reasonably assumed that the energy from their transmitter travelled in the same duct.

Though this experiment was performed only at 6.8 kHz, the transmitter is capable of working at frequencies up to 21 kHz and future research should show how this amplification depends on frequency, the time of day, transmitted power and the conditions prevailing in the magnetosphere.

Another amplification or wave growth process which has received attention recently is the transverse resonance instability. In this instability, which leads to the generation and growth of VLF waves in the magnetosphere, the high energy tail of the trapped particle distribution is unstable if the pitch angle distribution is anisotropic. The process is thought to explain ELF and VLF hiss at medium latitudes. Kennel and Petschek (*J. geophys. Res.*, **72**, 1; 1966) originally showed that particles with energies in excess of the magnetic energy for particles ($B^2/8\pi N$, where B is the magnetic field strength and N is the ambient plasma density) would be unstable to wave growth and that the instability would lead to particle precipitation and a limit to the fluxes of particles trapped in the magnetosphere. This limit to the numbers of trapped particles was considered important and in agreement with satellite observations. The existence of this limit is now questioned by Etcheto and her colleagues (*J. geophys. Res.*, **78**, 8150; 1973) who have established a self-consistent solution to the equations governing the wave growth and particle diffusion. This solution suggests that there is strictly no 'limiting flux' and that the equilibrium flux of trapped particles depends on the rate of injection of particles into the trapping region of the magnetosphere.

The amplifying and wave growth processes are clearly of increasing importance in this field for they contribute in different ways to both the strength of the transmitted whistler mode signal and the background noise which interferes with its reception.

Aspirin, Boston and Little Rock

from a Correspondent

IT may be asserted with some confidence that the genetically determined haemoglobin variants provide the most impressive roll-call of place names from all over the world, from Saskatoon to Sydney, and from Toronto to Tongariki. The appearance of aspirin in the title of this column, however, calls initial attention to a paper which appears to dispose of yet another proposed therapy for sickle cell anaemia. Starting from the established transfer, both *in vitro* and *in vivo*, of the acetyl group of aspirin to an ϵ -NH₂ group of lysine of serum albumin, Klotz and Tamm in 1973 had reported a similar transfer to haemoglobin, accompanied by a substantial increase in oxygen affinity. It was considered that this shift might be due to acetylation of the NH₂ terminal valines; a similar shift is observed following their carbamyla-

tion by cyanate, which is being intensively studied as a possible drug for the inhibition of sickling of sickle-cell anaemia red cells *in vivo* (see *Nature new Biol.*, **242**, 33; 1973).

De Furia, Cerami, Bunn, Lu and Peterson (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 3707; 1973) have re-examined the effect of aspirin on the oxygen affinity of haemoglobin. They find that although the acetyl group is indeed transferred, both *in vitro* and *in vivo*, there is no effect on the oxygen equilibrium of haemoglobin, either in solution or in intact red cells. Furthermore, patients on long-term aspirin therapy show no shift in the oxygen affinity of their blood. They also failed to observe any inhibition of *in vitro* sickling of deoxygenated sickle cell erythrocytes previously incubated with aspirin, and conclude that this drug is of no value in the treatment of sickle cell disease.

The gelation of sickle cell haemoglobin itself has been the subject of theoretical study. Minton (*J. molec. Biol.*, **82**, 483; 1974) has devised a thermodynamic model to account for the macroscopic solution properties of Hb-S in terms of microscopic structure and interactions. In this model step 1, the formation of a rod-like microtubular array, is treated as being equivalent to a precipitation. Step 2, the formation of the nematic gel phase, is treated as an isotropically-aligned transition in a suspension of interacting rod-like particles. By combining the two steps a qualitative temperature-composition phase diagram is obtained which provides a unified interpretation of many of the observed properties of Hb-S solutions.

In Hb-M(Boston) the distal histidines in the haem pockets of the α subunits are replaced by tyrosines; His E7(58) \rightarrow Tyr. The iron atoms of the abnormal α subunits remain in the ferric state to give a natural valency hybrid α_2^{+M} Boston β_2^{deoxy} . In heterozygotes for Hb-M(Boston) there is methaemoglobinemia because of the ferric α chains and cyanosis because of the low oxygen affinity of the normal β chains. Pulsinelli, Perutz and Nagel (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 3870; 1973) have now studied this variant by X-ray analysis. A difference electron density map of deoxy Hb-M(Boston) minus deoxy Hb-A shows that the ferric iron atom in the α subunit coordinated to the four nitrogens of the porphyrin and the phenolate group of the tyrosine. The normal bond to the proximal histidine F8 (87) is absent and the iron, which is therefore five-coordinate, lies on the distal side of the porphyrin ring (see figure). The rupture of this bond causes the F helix to shorten slightly "like a spring released from a tension that had kept it slightly un-

Stereochemical changes in the haem pocket of the α subunit on going from deoxy Hb to Hb-M(Boston) (from Pulsinelli *et al.*).

coiled". The resulting changes in tertiary structure of the α subunits stabilizes the deoxy or T structure of the haemoglobin tetramer, which lowers the oxygen affinity of the normal β subunits. Thus the clinical effects and many of the abnormal properties of Hb-M(Boston) can now be accounted for in structural terms.

Haemoglobin Little Rock is a high oxygen affinity variant which is unique in having normal Bohr effect and haem-haem interactions. Collaboration between Bare, Alben and Bromberg (Ohio), Jones and Brimhall (Oregon) and Padilla (Little Rock) (*J. biol. Chem.*, **249**, 773; 1974), has now established that the alteration in sequence is β His H21 (143) \rightarrow Gln. Since the β 143 histidine is an important binding site for the allosteric effector 2, 3-diphosphoglycerate, they have studied the effect of DPG on the oxygen affinity of Hb-Little Rock. They find that the DPG dissociation constant for deoxy Hb-Little Rock is about twice that for deoxy Hb-A, and the corresponding value for the oxy form about four times that of oxy Hb-A. They conclude, however, that the higher oxygen affinity of Hb-Little Rock cannot be explained solely in terms of reduced allosteric interaction with DPG, and that the Gln residues at β H21(143) must have a further specific effect on the oxygenation equilibrium.

Immunodepression in protozoan infection

from our Parasitology Correspondent

ANY ideas that patients with malaria or sleeping sickness readily succumb to other infections because of malnutrition associated with the disease are losing ground as more evidence accumulates to suggest that the immune response to other antigens is depressed

during protozoan infections. As long ago as 1962 it was realised that children suffering from malaria had diminished responses to tetanus toxoid (McGregor and Barr, *Trans. R. Soc. Trop. Med. Hyg.*, 56, 364; 1962) but the reasons for this were not investigated for another decade. Under experimental conditions, mice infected with malaria respond less well to tetanus toxoid than do controls (Voller, Gall and Manawadu, *Z. Tropenmed. Parasit.*, 23, 152; 1972) and this has been confirmed in children (Greenwood *et al.*, *Lancet*, i, 169; 1972). The mouse malaria model has provided considerable information on immunodepression during malaria infections and the antigens to which the immune response is diminished include not only standard preparations but also infectious agents such as Moloney leukaemia virus (Bamford and Wedderburn, *Nature*, 242, 471; 1973).

In laboratory models of trypanosomiasis, Goodwin and his colleagues (*Brit. J. exp. Path.*, 53, 40; 1972) found that infected mice and rabbits had reduced abilities to produce antibodies against sheep red blood cells and Urquhart and his associates (*Trans. R. Soc. Trop. Hyg.*, 66, 342; 1972) found that the rejection of the nematode worm *Nippostrongylus brasiliensis* was impaired in rats with trypanosomiasis. Immunodepression is less easy to test in human trypanosomiasis, but Greenwood, Whittle and Molyneux (*Trans. R. Soc. Trop. Med. Hyg.*, 67, 846; 1973) were able to examine 38 patients with Gambian sleeping sickness using skin tests antigens and *Salmonella typhi* vaccine. The humoral and cellular responses were both less in these patients than in 43 uninfected controls. None of the patients was suffering from malnutrition.

Immunodepression has also been shown to be associated with experimental toxoplasmosis by Strickland and his associates (*J. infect. Dis.*, 126, 54; 1972). Infected mice were less able to mount an immune response against malaria than controls.

A general pattern seems to be emerging in which immunodepression is a constant feature of protozoan infections. The effects need not necessarily always be harmful for autoimmune diseases may be prevented in infected animals as in the cases of allergic encephalomyelitis and trypanosomiasis (Allt, *et al.*, *Nature*, 223, 197; 1971) and spontaneous autoimmune disease of New Zealand mice and malaria (Greenwood and Voller, *Clin. exp. Immunol.*, 7, 805; 1970).

The mechanisms of immunodepression are still obscure despite the wealth of examples available for study. Antigenic competition is thought to be one explanation, but the possibility of

specific interference with the function of T cells is receiving attention (Bamford and Wedderburn, *Nature*, 242, 471; 1973). The problem deserves urgent attention because of the possible danger involved in vaccinating children and others infected with a range of tropical diseases. The relations between malaria and Burkitt's lymphoma have already received considerable attention (Ziegler, *et al.*, *Trans. R. Soc. Trop. Med. Hyg.*, 66, 285; 1972).

A curious difference between parasitologists and virologists exists in this field. Parasitologists talk of immunosuppression and virologists of immunodepression. The experimental evidence points to depression rather than suppression; the virologists' term is preferable and they used it first.

Interpreting heat flow

from our Geomagnetism Correspondent

IN the sense that heat plays a part, and very often a crucial part in all internal terrestrial phenomena, study of the Earth's thermal processes may be regarded as the most important of all branches of geophysics. But by the same token it is a difficult subject to come to terms with. Heat sources and sinks abound; yet data are sparse, difficult to determine and even more difficult to interpret. The very complexity of the situation militates against the drawing of significant conclusions; and as two new reports demonstrate, heat flow workers, through no fault of their own, can easily appear as the thermal counterparts of the Ancient Mariner who found "water, water everywhere, nor any drop to drink".

For example, Sass *et al.* (*Earth Planet. Sci. Lett.*, 21, 134; 1974) have taken advantage of geological investigations into possible sea level canal routes to measure heat flows in eastern Panama and north-western Colombia, the area where the Cocos, Nasca and Caribbean plates interact. There are, of course, few thermal situations more complex than the zones in which three lithospheric plates meet, for in such regions heat sources and sinks lie in close proximity to each other. A relatively cold lithospheric plate being thrust under an adjacent plate acts as a sink, but shearing along the boundaries between plates may produce frictional heating and thus a contribution to measured heat flow. Moreover, if in addition partial melting occurs, surface heat flow may be increased by the upward penetration of magma. These processes occur where two plates meet; at triple points they are even more intermingled.

In the present case Sass and his colleagues have obtained twelve new heat

flow values—three from the Canal Zone and three from each of three prospective sea level canal routes (routes 10, 17 and 25). In the vicinity of route 10, which lies 50–100 km west of the present Canal Zone, the average heat flow is high at $1.77 \mu\text{cal cm}^{-2}\text{s}^{-1}$ (h.f.u.). Previous work has shown that heat flow is also high south of Panama where it is associated with relatively young oceanic crust near the East Pacific Rise and the Galapagos Rift zone and with recent tectonic activity in the Panama Basin. The new land values, however, may be explained in terms of both the plate tectonic situation and the region's geological features. Sass *et al.* thus suggest that the high heat flow from route 10 may represent the easterly limit of a high heat flow zone associated with the Cretaceous volcanic centres which extend westwards into Costa Rica and Nicaragua.

Route 17, which lies 100–150 km south-east of the Canal Zone, and the Canal Zone itself are associated with heat flow values in the range 0.94–1.40 h.f.u. These are consistent with the low-to-normal values previously found at sea in the Caribbean plate to the north where, because of the oceanic character of the basement, it seems probable that most of the observed heat comes from mantle sources. The maximum contribution from the crust is thus probably no higher than 0.1–0.2 h.f.u. Some 100–150 km further south-east, along route 25, however, heat flow is even lower (0.66–0.70 h.f.u.). Because the average here (0.68 h.f.u.) is lower than even the theoretical 'mantle' heat flow found by Roy *et al.* (*In The Nature of the Solid Earth*, McGraw-Hill, 1972) for the Palaeozoic craton of North America, the observed surface heat flow presumably reflects the heat sink associated with the underthrusting Nasca plate.

In summary then, the new heat flow values obtained by Sass and his colleagues appear to be consistent generally with plate tectonics and surface geology even though they do little by themselves to sort out the complex interactions giving rise to them. By contrast, the analyses reported by Negi *et al.* (*Earth Planet. Sci. Lett.*, 21, 143; 1974) seem to be inconsistent even with previous work in the same field. Some years ago Horai and Nur (*J. geophys. Res.*, 75, 1985; 1970) carried out correlation and regression analyses of terrestrial heat flow (q) and thermal conductivity (k) which suggested that for many continental areas q and k are not independent. In fact, q correlated positively with k , a phenomenon which Horai and Nur put down to the fact that, in an inhomogeneous crust, heat flow will converge where the crust is more conductive. They further proposed that since q is proportional to heat production (A), k must also be proportional to A —a conclusion whose

necessity was later disputed by Naidu (*J. geophys. Res.*, **76**, 3426; 1971) but reaffirmed by Horai and Nur (*J. geophys. Res.*, **76**, 3428; 1971). A further conflict then came to light when it became clear that although Horai and Nur had found that the positive q - k correlation applied to the Indian peninsular shield, Gupta and Rao (*Bull. natn. Geophys. Res. Inst.*, **8**, 87; 1970) had already found no such correlation in the Indian Precambrian crystalline regions.

Continuing along similar lines, and to make matters even more confused, Negi and his coworkers have found that for all Indian sedimentary basins q correlates with k negatively. On the other hand, a positive correlation between heat flow and geothermal gradient (G) agrees with that found by Gupta and Rao for Indian Precambrian crystalline areas. Finally, heat flow is found to correlate negatively with crustal thickness.

What does it all mean? Negi *et al.* conclude that for sedimentary basins, at least, the negative correlation between q and k implies very little heat generation in the crust; in other words, most of the observed heat comes from below. The observed correlations between q , k , G and crustal thickness are often presumed to be due to variations in crustal thickness which produce a variable shielding effect on subcrustal heat. These are rather mundane conclusions to emerge from so much work; and it is difficult to judge their importance. Clearly, however, the parameters involved are very basic to the whole question of variations in heat flow; and so it would be helpful if someone would put all the data together and, if possible, explain just what is to be made of them.

Semiconductors in the human body?

from our
Solid State Physics Correspondent

It was realised about 20 years ago that the production of energy from oxygen in the cell mitochondrion was possibly the result of direct electronic transport through haemoproteins rather than the interaction of mobile ions through an aqueous medium (see, for example, Szent-Györgyi, *Discuss. Faraday Soc.*, **27**, 111; 1959; Carden and Eley, *ibid.*, 115). It was thus necessary to think about a sort of wet solid-state physics which could embrace reasonably high rates of transport of free electrons or holes through biological solids, especially through certain haemoproteins involved in respiration. Szent-Györgyi proposed a theory that a suitable conduction band could be produced by orbital overlaps in amino acid chains and one could predict from

this theory that proteins might achieve conductivities in the semiconductor range. The theory was conceptually very attractive but was not widely taken up, largely because it was not at the time susceptible of proof, nor had any investigation ever revealed a way of making analogous but simpler organic materials conduct to the level required.

Now, at least, one biological material has been shown to have a strikingly large conductivity when correctly excited. McGinness, Corry and Proctor, of the University of Texas Cancer Center, Houston, report in *Science* (**183**, 853; 1974) that melanins can be made to 'switch' from a poorly conducting to a highly conducting state at fairly low electric fields (say from 10^5 Ω cm to 10^3 Ω cm at a field of 3×10^3 V cm $^{-1}$). This remarkable phenomenon occurs both in melanin made synthetically from tyrosine and in that extracted from a human melanoma. The large conduction is not destructive in any way and is reversible; according to some tests, conduction seems to be electronic rather than ionic. Also tests of a few other likely biological materials in the same form (a compressed solid pellet inside a quartz tube, mildly hydrated and of length ranging from 0.1 to 10 mm) suggest that the effect is confined to the melanins and the authors note a similarity in the I - V characteristics of the sample to those of some amorphous inorganic semiconductors which undergo 'threshold switching'. But apart from the major difference in the electric field at which the threshold effect occurs (of the order of 10^3 V cm $^{-1}$ for melanin and 10^5 V cm $^{-1}$ for chalcogenide glasses), the current theory of the inorganic switching phenomenon rests on filamentary conduction, leading to a controlled degree of segregation of the constituents of the glass (for example, segregation of pure tellurium from Ge-Te alloys) and possibly strong injection at the electrodes under the high local fields (Bosell and Thomas, *Phil. Mag.*, **27**, 665-81; 1973).

Neither of these effects seems even likely in the system described, especially since the switching becomes unstable at thicknesses of chalcogenide greater than a few micrometres. Thus, the suggestion of McGinness *et al.* that melanin in the human body can be a cause rather than a by-product of disease and that its mode of action can be related to this 'electronic device' action is probably premature, especially considering the preliminary nature of the experiments. A revival of discussion on *in vivo* electronic effects in some biological materials associated with oxidation-reduction is, however, welcome if only because science has perhaps moved far enough since the 1950s that it can now devise adequate tests for the basic

theories of transport in wet solids. Also a new approach to the treatment of melanotic diseases may well be stimulated by this particular revival of an intellectually stimulating discussion.

How to wrap up and get your female

from our
Animal Behaviour Correspondent

MICHAEL and Barbara Robinson spent a year in New Guinea observing the giant wood spider, *Nephila maculata* (Fabricius). Their report (*Smithson. Contrib. Zool.* No. 149; 1973) contains some remarkable facts of spider life, including a description of the strange method of courtship. As can be seen from the photograph, the male is much smaller than the female (4-6 mm body length as opposed to 40-50 mm) and before actual copulation, he goes through an elaborate 'lashing' of the female, weaving silk onto her body. The male may spend the greater part of two days standing on the female and during this time periodically indulges in intense bursts of activity, laying down silk threads between the female's legs and body. The female rarely gives any response at all to this silk deposition, after which the male copulates.

It would seem logical to suppose that the functional significance of binding up the female in this way would be that it in some way restrains her and prevents her from attacking the male. But although a great deal of silk is laid down around the leg bases, this does not seem to hamper the female very much, for she can rush off on predatory excursions even after the silk

Male on dorsal surface of the abdomen of a female *Nephila maculata*. Silk lines are visible on the thorax of the female leading to the leg bases and abdomen.

has been heavily deposited. The Robinsons suggest that the silk may in fact prevent the female from bending at the waist, which would in turn prevent her from picking off the male while he is copulating.

As well as describing the unique courtship, the Robinsons also describe the kleptoparasites of *Nephila*, spiders of other species which live in the web and steal food caught by the host. Often, the kleptoparasites were seen to rush in and start feeding while *Nephila* was actually subduing or wrapping its prey, a somewhat hazardous past-time as the kleptoparasites themselves often became enmeshed.

Origin of antibody diversity

from a Correspondent

THE apparently inexhaustible repertoire of antibody-combining sites possessed by vertebrate animals raises an important question. Does the germ line genome code for all antibody genes (germ line theory), or is diversity generated during the life of an individual by mutation of a restricted number of germ line genes (somatic theory)? Argument surrounding this question has raged backwards and forwards ever since the discovery that heavy and light chains of immunoglobulin molecules are composed of constant (C) and variable (V) regions (Hiltschmann and Craig, *Proc. natn. Acad. Sci. U.S.A.*, **53**, 1403; 1965). What is agreed is that separate genes code for C and V regions and that there is only a single C gene for a given constant region (Ig class or subclass) sequence. The question may therefore be reframed in terms of V genes: are all the conceivable V genes carried in the genome or are they somatically generated?

Perhaps the strongest argument against the germ line theory is the existence of allelic markers and species-specific amino acid sequences in V regions. But this argument is inferential and it has long been the hope that direct experimental evidence could be brought to bear on the question. This now seems to be provided by Premkumar, Shoyab and Williamson (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 99; 1974). In principle, the authors have isolated heavy chain messenger RNA and have estimated by hybridisation the number of C and V genes in isolated DNA. Their results, they argue, firmly support the germ line theory.

An absolute prerequisite for this type of experiment is that the isolated messenger RNA is pure and labelled at high specific activity so that hybridisation can be done in great excess of DNA. In order to achieve this, cells

from mouse myeloma MOPC 315 were labelled *in vitro* with radioactive uridine and cytidine, and then mRNA for the α chain was isolated from the poly(A)-containing fraction taking advantage of its specific interaction with immunoglobulin (Stevens and Williamson, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 1127; 1973; *J. molec. Biol.*, **78**, 517; 1973). The resulting RNA sedimented largely as a single peak at 16-17S and, after sonication to 6-7S, was hybridised with about a 10^7 excess of cold DNA, also sonicated to 6.4S.

Using whole mouse embryo (the actual age is not given) as a source of DNA, a biphasic C_{ot} curve resulted. Approximately 70% of the input RNA was hybridised at the maximum, and 20% was found in the low C_{ot} transition. It is here that the authors make a crucial assumption, namely that the low C_{ot} transition (C_{ot} of 1.5) corresponds to hybridisation of V genes and the high C_{ot} transition (C_{ot} of 10^3) represents hybridisation to C genes. If this assumption is wrong, then so are the conclusions. Their reasons for making this assumption are that the RNA is pure, and that the ratio of hybridisation found in the two regions of the C_{ot} curve (0.29) is close to the expected figure of 0.25. The possible occurrence in the isolated RNA of RNA sequence stretches which do not code for C or V region sequences is obviously a source of uncertainty.

Similar, but not quite as impressive, results were obtained when BALB/C spleen or myeloma MOPC 315 DNA was used for hybridisation. Given the basic assumption made, the C_{ot} values correspond to 4-8 C genes and about 5,000 V genes.

Although sequence analysis indicates considerable cross-homology of mouse V_H regions, the figure of 5,000 V_H genes if accepted, must be a lower estimate. If, as the authors assume, that there are an equal number of V_L genes and that V_L and V_H regions can associate at random, then there is sufficient information for at least 2.5×10^7 antibody-combining sites. Even allowing for inefficiency, this would seem to be a high enough figure to account for antibody diversity. The authors conclude that their data "obviates the necessity to search for somatic generators of diversity. Questions concerning the maintenance and control of a large V-gene pool in the germ line and the expression of V genes by interaction with C genes can now be brought more clearly into focus".

Until the fraction of RNA hybridising at the low C_{ot} transition is actually identified as specifying V region, however, proponents of the somatic theory are unlikely to be satisfied and the argument will continue with unabated force.

Sense of supercoils in closed circular DNA

from a Correspondent

AN interesting study on the sedimentation of denatured closed circular DNAs with different degrees of strand interwinding has been made by Schmir, Révet and Vinograd (*J. molec. Biol.*, **82**, 34-35; 1974). From their results these authors have deduced the absolute sense of the supercoils in closed circular DNA and are able to confirm that the binding of intercalating dyes unwinds, rather than winds up, the DNA helix.

Double stranded DNA in the form of closed circular superhelices was first discovered in extracts from polyoma virus in 1963, and has subsequently been shown to exist in a wide variety of organisms. The biological significance of the closure is not yet clear but these molecules have a number of interesting structural and chemical properties. The superhelical structure imposes upon the DNA molecule a topological restraint usually expressed by saying that, for a given molecule, the total number of rotations of one strand about the other, the topological winding number, is invariant. Thus a modification in the number of turns in the basic double helix, for example by changing the ionic strength of pH of the environment, or by the addition of intercalating dyes, is accompanied by an equal and opposite change in the number of superhelical turns. The introduction of a single scission into one of the DNA strands results in a circular DNA with no superhelical structure. The superhelical DNAs sediment at a higher rate than the nicked DNAs, the exact value of the sedimentation coefficient, s , being a complex function of the superhelix density, σ (the number of superhelical turns per ten base pairs).

Vinograd, Lebowitz, Radloff, Watson and Laipis (*Proc. natn. Acad. Sci. U.S.A.*, **53**, 1104; 1965) studied the change in s for a DNA in which the topological winding density, $A \approx 1$, as the pH of the environment is progressively increased and the DNA becomes more denatured. At pH ≈ 12.5 , the DNA duplex is completely denatured, extensive positive supercoiling occurs and the sedimentation coefficient in these conditions is 2.1 times greater than that of a single stranded, circular molecule having an equivalent molecular weight. This greatly increased sedimentation coefficient can therefore be attributed directly to the winding of one strand about the other.

In the new article, Schmir *et al.* extend these results by studying the sedimentation coefficients, at high pH values, of DNAs with different topological winding densities. A number of closed circular DNAs with A values

varying from 0.99 to 0.89 were prepared from simian virus (SV40) and phage PM2 DNAs. This 10% decrease in topological winding density results in a decrease of approximately 5% in the alkaline sedimentation coefficient, which can be understood in terms of a small negative change in the superhelix density of the denatured molecule. The data connect smoothly with similar results obtained by Sebring, Kelly, Thoren and Salzman (*J. Virol.*, **8**, 478; 1971) for DNAs with A values from 0.6 to 0.15. The range is completed by the inclusion of a point for $A \approx 0$ computed from a relation proposed by Wang (*Biopolymers*, **9**, 489; 1970). As A decreases from 1 to 0, the value of relative s changes from 1 to 0.45.

The A values quoted here were determined on the assumption that for all naturally occurring closed circular DNAs, $A \leq 1$. This arises from the interpretation of the experimental results obtained from studies on the binding of intercalating dyes to superhelical DNA in accordance with the proposal by Lerman (*J. cell. comp. Physiol.*, **64**, suppl. 1, 1; 1964) and Fuller and Waring (*Ber. Bunsenges. phys. Chem.*, **86**, 805; 1964) that intercalating dyes unwind the DNA helix. The observed data are then consistent with a model in which the superhelix density σ is initially less than 0 and A is not greater than 1.

The recent assertion by Paoletti and LePecq (*J. molec. Biol.*, **59**, 43; 1971) that ethidium bromide winds up the DNA helix has the corollary that $A \geq 1$ in naturally occurring closed circular DNAs. Schmir *et al.* are able to refute this suggestion completely. First, they point out that the data of Sebring *et al.* were derived from replicating intermediates of SV40 DNA which were extensively unwound while nicked during the replicating process. There can therefore be no doubt that for these DNAs, $A \ll 1$. In addition, the point computed by Wang is unaffected by considerations of winding or unwinding the helix. Second, they have carried out dye titrations with a closed circular replicative mitochondrial DNA before and after removal of a short progeny strand (Révet, Schmir and Vinograd, *Nature new biol.*, **229**, 10; 1971). These experiments indicated quite clearly that less ethidium bromide was required to relax the supercoiled DNA molecule in the presence of the progeny strand than was required after its removal. The removal was achieved in such a way that the parent DNA did not become denatured and was able to rewind into its original structure. The results of Schmir *et al.* indicate unequivocally that the insertion of a displacing progeny strand and the binding of ethidium bromide act in the same direction, that is, they both unwind the DNA helix.

Schmir *et al.* conclude therefore that the initial superhelix density must be negative, A is less than 1 and the sense of the supercoils in natural closed circular DNA is negative, not positive as proposed by Paoletti and LePecq.

The results obtained during the past ten years on the binding of certain dyes to superhelical DNAs can be interpreted almost without exception in terms of a model in which the bound dye produces an unwinding in the DNA double helix. In view of the extreme sensitivity of superhelical DNA to small changes in its structure, this technique might in the future provide a means of distinguishing between the different modes of interaction of DNA and a variety of dye molecules.

Torpor in an Andean hummingbird

from our Animal Ecology Correspondent

THE attraction of hummingbirds to physiologically-inclined ecologists is easy to understand. How do these tiny, active creatures manage to survive in the inhospitable habitats of some of the world's highest mountains? Calder and Booser (*Science*, **180**, 751; 1973) found that nocturnal torpor during incubation was not uncommon at times of energy depletion. When the ambient temperature was low and heavy rain precluded nocturnal foraging, a gradual lowering of the body temperature ensured the sufficiency of the bird's energy reserves to see it through the night.

Another physiological adaptation of obvious survival value has been reported by Carpenter (*Science*, **183**, 545; 1974) who worked with a population of the hillstar hummingbird *Oreotrochilus estella*, which lives at a height of between 3,800 m and 4,300 m in the high Andes. By day the birds forage for nectar from a variety of local and exotic plants. At night they roost communally in caves and can readily be observed with little disturbance. Carpenter recorded body temperatures from a small group of birds: most were recorded between one and eight times during either the summer or winter study periods; a few were recorded in both summer and winter. Torpor was defined as a significant drop from the normal body temperature of about 30° C. In summer the average duration of nocturnal torpor was 7 h and during the winter 10 h. This difference is significant in spite of the fact that winter nights were 15 to 90 min longer than summer nights. Calder and Booser reported that body temperature during nesting torpor never sank below 6.5° C. The same was true in Carpenter's study, even though ambient temperature sometimes dropped to 3° C.

Why is torpor used more extensively

Zoological Society of London

Stripe breasted starthroated hummingbird (*Heliomaster squamosus*), a different species of hummingbird from that described by Carpenter but it shows the characteristic feeding behaviour of these birds.

by the birds in winter? One of the winter groups of birds lives in an area surrounded by blooming *Eucalyptus* trees, from which they fed heavily. Incidence and duration of torpor was the same as in other local populations with less well endowed larders. It seems as if energy depletion is not a cue for torpor. Nor does temperature seem to be the trigger. In summer the ambient temperatures in the roosts varied from 3.5° C to 13° C, and in winter from 3.0° C to 13° C. This high winter temperature is thought to be exceptional; winter roost temperatures are normally near freezing.

Carpenter suggests that although the difference between summer and winter ray length is brief, it is sufficient to act as a photoperiodic cue for a circannian rhythm. Such a rhythm would have survival value for a species living in an area where nocturnal temperature is seasonally low and in which the day time temperature gives no indication of the ensuing night time level. By entering torpor as soon as it roosts, a bird is capable of regulating its body temperature for long periods should the ambient temperature drop much below 6.5° C—a clever way of extending fuel contingency reserves without increasing fuel capacity.

Probing the secrets of ionic channels

from a Correspondent

SINCE Galvani's fortuitous joining of brass hook, iron plate and frog in 1786, the lure and mystery of 'animal electricity' have been reduced to the molecular secrets of so-called cation channels, which intermittently allow these ions to cross membranes. Recent chemical and electrical probes of the structure of these channels were the main topics of a meeting at the Royal Society on March 13-14.

The simplest model of a channel is a pore, a few Angstroms in diameter, capped by one or more gates which open or close the pore depending on the recent history of the voltage across

the membrane. B. Hille (University of Washington) summarised the evidence for such models for the sodium and potassium channels, as gleaned from the voltage clamp technique pioneered by Hodgkin and Huxley more than 20 years ago. Hille's and other data (Woodhull, *J. gen. Physiol.*, **61**, 687; 1973) suggest the presence of a carboxylic acid group inside the sodium pore.

The same carboxylic acid group was detected by J. M. Ritchie (Yale University) and colleagues, using a powerful technique not requiring electrical measurements (*J. Physiol.*, **232**, 53P; 1973). They deduced its presence from the competitive binding of tritiated tetrodotoxin (TTX) and other ions to the sodium channel. TTX binding survives solubilisation of membranes in Triton X-100, but the sodium channels have yet to be purified by this route. By contrast, the much tighter binding of α -bungarotoxin to acetylcholine receptors has aided their purification, as discussed by D. P. Green (University College, London).

The lack of a specific toxin for the potassium channel was widely lamented, though vagaries of the potassium currents in nodes of Ranvier and in cardiac muscle were described by B. Frankenhaeuser (Karolinska Institute, Stockholm) and D. Noble (University of Oxford). P. F. Baker (University of Cambridge) discussed delayed movements of calcium following action potentials, which he thinks are related to those activating transmitter release at synapses. L. G. M. Gordon and D. A. Haydon (University of Cambridge) talked about quantal permeability changes in artificial membranes, and G. K. Radda (University of Oxford) described the use of fluorescent probes.

A. von Muralt (Universität Bern) and J. V. Howarth (Marine Biological Association, Plymouth) summarised the slight optical and thermal changes in membranes during action potentials. These, it was concluded, reflect the consequences rather than the causes of the underlying permeability changes.

The latest and most controversial technique involves measuring the tiny displacement currents visible in voltage-clamped axons when the usual ionic currents are blocked. C. M. Armstrong and F. Bezanilla (University of Rochester) think that these are 'gating currents', caused by the movement of those charged particules or dipoles thought to open and close the sodium channel (*Nature*, **242**, 459; 1973), and they reported, as supporting evidence, that perfusion of an axon with $ZnCl_2$ removed reversibly both sodium and displacement currents. Both currents could also be inactivated by depolarising pulses, and this effect was removed by pronase.

H. Meves (MBA, Plymouth) took

issue with this interpretation, pointing out that other charged groups, which may vastly outnumber the gating groups, could easily obliterate the true gating current. Furthermore, although the qualitative behaviour of the measured displacement currents is acceptable, he observed that they depart from expectations in several quantitative respects. W. K. Chandler (Yale University), who first studied similar but slower currents in muscle (*Nature*, **242**, 244; 1973), suggested that they play a part in excitation-contraction coupling.

If gating currents are what their name implies, then their magnitudes may be used to calculate the density of sodium channels, if one assumes six net charges per channel as given by Hodgkin and Huxley. R. D. Keynes (University of Cambridge), who organised the conference, and E. Rojas (MBA, Plymouth) estimated on the basis of both displacement currents (*J. Physiol.*, **233**, 28P; 1973), and TTX binding, that the squid giant axon has about 400 sodium channel per μm^2 . A. L. Hodgkin (University of Cambridge), using a dimensional argument, suggested that the density of sodium channels in nerve should be about 1,000 per μm^2 , if the conduction velocity is to be maximised. These numbers are much higher than the 13 channels per μm^2 originally estimated on the basis of TTX binding to lobster nerve (Moore, Narahashi and Shaw, *J. Physiol.*, **188**, 99; 1967) and popularly subscribed to until about the middle of this meeting. The discrepancy suggests either vast species differences, or errors in the interpretation of TTX binding studies (tritiated impurities were mooted), or that 'gating' currents contain a large component that has nothing to do with gating. *Caveat emptor.*

Cloning for obesity

from our
Molecular Genetics Correspondent

NATURAL selection of organisms for traits desirable under particular circumstances is of course a well established feature of evolution. And artificial selection has been used both to isolate mutants of bacteria or eukaryotic cells in culture and to permit only cells possessing certain functions to survive. Cloning cells in culture can be used to isolate lines with enhanced or reduced expression of functions which can be followed quantitatively (rather than the all or nothing expression of many mutants). In a classic series of experiments some years ago, the 3T3 and 3T6 cell lines of mouse fibroblasts were derived with different responses to inhibition of growth by culture conditions. By cloning sublines of the 3T3 cell, Green and Kehinde now report in

the March issue of *Cell* (**1**, 113; 1974) that they have isolated two sublines which accumulate large amounts of triglyceride fat in the resting state.

Illustrating their article with some striking colour photographs, Green and Kehinde demonstrate vividly that the cells of these sublines resemble adipose cells in accumulating large amounts of lipid in their cytoplasm. The initial observation which led to these experiments was the presence of a few cells possessing liquid droplets in resting cultures of 3T3 cells; when resting cells are transferred to conditions which promote growth, the fatty cells are not found among the growing progeny, although such cells reappear when the culture again enters the resting state. By isolating areas rich in lipids from resting cultures, growing these isolates and then repeating the process when the culture reached the next resting phase, Green and Kehinde obtained cultures which were progressively richer in fatty cells. Eventually, they isolated two clones which accumulate lipid in large amounts.

When resting cultures of these cells are transferred to conditions which stimulate growth, the most fatty cells may survive for a few days but usually disintegrate eventually. The presence of large amounts of fat presumably interferes with the processes of cell division. But cells possessing less fat may reinitiate division; and after a successful division — sometimes mitosis fails in cytokinesis — the amount of lipid is diluted and then continues to decrease in each cell during successive cycles; except for the extremely fatty cells, therefore, both the lipid-accumulating sublines can be propagated indefinitely.

What is the cause of the lipid accumulation? Possible explanations, at present unresolved, include excessive uptake from the culture medium, increased synthesis within the cell or decreased degradation. Because the accumulation of lipid is inhibited by lipolytic agents such as dibutyryl cyclic AMP, Green and Kehinde suggest that one practical use of these lines may be to provide a means to test drugs for possible effects on lipid metabolism. And even more intriguing are some of the possible theoretical implications of the properties of these cells. What genetic change may underlie the conversion of a cell derived from the fibroblast into one apparently akin to the cells of adipose tissue? How is this change related to the usual processes of differentiation in developing mouse cells and can such changes be found for other phenotypes? The development of a differentiated phenotype in culture represents an important contrast with the more usual consequence of tissue culture.

Spatial resolution of ERTS images by computer

Alden McLellan & William Kuhlow

Space Science and Engineering Center, Institute for Environmental Studies, University of Wisconsin, Madison, Wisconsin

The authors discuss a solution to one of the problems concerned with the use of the large amounts of data now available from remote sensing satellites.

A PERSISTENT problem in the remote sensing of Earth resources is the difficulty of gaining efficient access to the vast quantities of data which have been generated. Second only to this problem is that of displaying the results in a form convenient for analysis. Ever since the advent of remote sensing satellites, one of the aims of imagery analysis has been to modify the data in order to delineate and enhance specific features within a composite display. The aim of many investigators of data handling is to develop a man-computer integrated system for quickly and accurately enhancing and interpreting a large volume of data from an Earth resources satellite. Since the early 1960s, there has been extensive research on the development of spectral signature and pattern recognition theory in processing multispectral data. The thrust of this research has been to develop computer software packages to analyse large amounts of data generated by multispectral scanning instruments. It has been only recently, however, that image-display man-computer hardware systems have been developed.

Feasibility

The University of Wisconsin's Space Science and Engineering Center (SSEC) has demonstrated the feasibility of the Man-computer Interactive Data Access System (McIDAS) which has rapid data storage, access, display and analysis techniques applicable to many areas of satellite data processing. In this field, it is of considerable value to reference small subsets of these data in a fast and economical way, with accompanying observation and guidance by a human operator who interacts with the system. The advantage of the McIDAS system in the analysis of ERTS data is that the operator can see the data displayed on a television screen in a form suitable for easy interpretation by varying such quantities as the brightness and colour enhancement functions, time lapse motion and scale sizes. He can make the appropriate judgments, then communicate exact coordinates and instructions for processing of the digital data. In fact, the system always has access to the full precision data, so that maximum accuracy is always possible.

We are developing the software programs specifically for this system to analyse remote sensing data from satellites for natural resource inventory purposes and for monitoring changes in land use. Normally, investigators of Earth resources use aerial photographs to obtain inventory estimates of the required accuracy but not without expending time in the preparation of photographs, tedious interpretation of them and data handling. Lins and Milazzo¹ have described the use of multispectral photography for detecting land-use change. Wray² has made a comparative study of metropolitan regions using ERTS imagery; he states that the imagery shows great promise for the inventory of gross land use and the monitoring of changes in land use³.

The purpose of this paper is to present results from McIDAS showing the spatial resolution that can be obtained from ERTS-1 digital data by the display of urban images appropriate for identification of land use.

Four reels of ERTS-1 system corrected computer compatible tapes from the multispectral scanner (MSS), containing a scene of eastern Wisconsin taken on September 14, 1972, was made available to us by NASA. After modifying the data format for the McIDAS system, the Milwaukee metropolitan area was displayed in all four channels sequentially. A number of images were then manually enhanced by means of a teletype keyboard in which various levels of brightness values of the raw ERTS data were transformed to a chosen level of brightness within the dynamic range of the Muirhead PhotoFax Receiver. In the case of the pictures shown here, this involved 128 brightness levels from the MSS 5 channel transformed nonlinearly into 256 levels for the Muirhead Receiver. By using a number of trial and error non-linear enhancement curves to display the images on the McIDAS CRT, we were able quickly and economically to find the enhancement curve suited to the display of urban imagery in such a way that a number of recognisable features can be seen.

In Fig. 1, the major highways and roads leading to Milwaukee can be easily identified. The downtown area is located near the centre of the picture where East-West Interstate 94 turns South. An effluent plume into Lake Michigan can be seen immediately to the south-east of the downtown area just beyond the place where the Menomonee and Milwaukee Rivers merge. Other land features can also be seen, such as the Milwaukee County Stadium and the Forest Home Cemetery.

The area shown in Fig. 2 is one-fourth that encompassed by Fig. 1. In Fig. 2, the individual data points which make up the imagery become somewhat discernible. The plume at the estuary of the rivers, as well as the variation in reflected radiance from Lake Michigan near the shoreline east of Mitchell Field, is more apparent than in Fig. 1.

In Fig. 3, the individual ERTS data points are now quite evident. Mitchell Field appears here as a pattern of blocks.

Fig. 1 ERTS-1 Mufax picture from McIDAS digital computer enhancement of Milwaukee, Wisconsin. MSS 5 red visible channel taken on September 14, 1972. The picture comprises 360 ERTS scan lines (27.4 km) and 540 ERTS elements (30.8 km). a, Milwaukee river; b, Lake Michigan; c, Menomonee river; d, stadium; e, plume; f, highway 94; g, cemetery; h, Mitchell Field.

FIG. 2 ERTS Mufax picture from McIDAS digital computer enhancement of central and south Milwaukee. MSS 5 red visible channel taken on September 14, 1972. The picture comprises 180 ERTS scan lines (13.7 km) and 270 ERTS elements (15.4 km). *a*, Pier; *b*, plume; *c*, highway 94; *d*, Lake Michigan; *e*, cemetery; *f*, golf course; *g*, Mitchell Field.

The limits to the ability of ERTS to resolve features is clear; any further enlargements would not improve spatial resolution for the viewer. Other enhancement curves would, however, help delineate particular features not considered here.

Our software programs developed so far allow for three sizes of image field which represent the magnification ratios of 1:2:4, designated by the last digit on the annotation block in the three figures as 3, 2 and 1 respectively. The following information concerns Fig. 3. Information corresponding to Figs 1 and 2 can be obtained simply by using the scale factors 4 and 2, respectively.

In Fig. 3 the total image field represents 90 ERTS scan lines with 135 ERTS samples comprising each line. The 90 lines \times 135 samples represents a physical field size of approximately 6.8 km \times 7.7 km, respectively. Because of the size of the individual data points represented in the scanning display, each ERTS element had to be repeated twice to ensure that the proportions of the imaged field would correspond closely to the actual geographic proportions. The scaling, however, is still not quite exact. In the figures, the vertical dimension of the image is 'stretched' by 6.8% with respect to

FIG. 3 ERTS-1 Mufax picture from McIDAS digital computer enhancement of South Milwaukee. MSS 5 red visible channel taken on September 14, 1972. The picture comprises 90 ERTS scan lines (6.8 km) and 135 ERTS elements (7.7 km). *a*, Lake Michigan; *b*, golf course; *c*, Mitchell Field.

the horizontal dimension. The enhancement curve for each of the figures shown was:

Raw			
ERTS	0 to 7	\rightarrow 0	} Enhanced display
digital	8 to 64	\rightarrow 0 to 255 (linear)	
data	65 to 128	\rightarrow 255	

We thank Mr Ralph DeDecker for developing the software programs, Professor James Clapp for use of the ERTS digital tapes and Professor Verner E. Suomi and Mr Thomas O. Haig for discussions.

Received November 8, 1973.

Mesozoic thermal events in southeast China

Bor-ming Jahn

Geochemistry Branch, NASA Johnson Space Center, Houston, Texas 77058

The first Rb-Sr age data are reported for Mesozoic batholiths in southeast China. Two thermal episodes are recognised (165 ± 13 and 90–109 Myr) and can be correlated with the periods of rapid spreading of the Mesozoic Pacific Ocean floor as proposed by Larsen and Pitman.

FROM the study of Mesozoic magnetic lineations in the western Pacific, Larsen and Pitman¹ and Larsen and Chase² postulate that, during the late Mesozoic, the Pacific sea

floor was spreading from at least five spreading centres joined at two triple points. Most of the Pacific Basin today is occupied by the expanded Pacific plate of the late Mesozoic system. This implies that an area equal to most of the Pacific Basin has been subducted beneath the surrounding continents since the early Cretaceous. Larsen and coworkers also correlate the Keathley magnetic lineations of the North Atlantic with the Hawaiian lineations of the Pacific and suggest that the Bay of Biscay opened during the interval between 150 and 110 Myr BP and the drift in the South Atlantic was initiated at sometime during the interval from 110 to 85 Myr BP. More importantly, with their magnetic

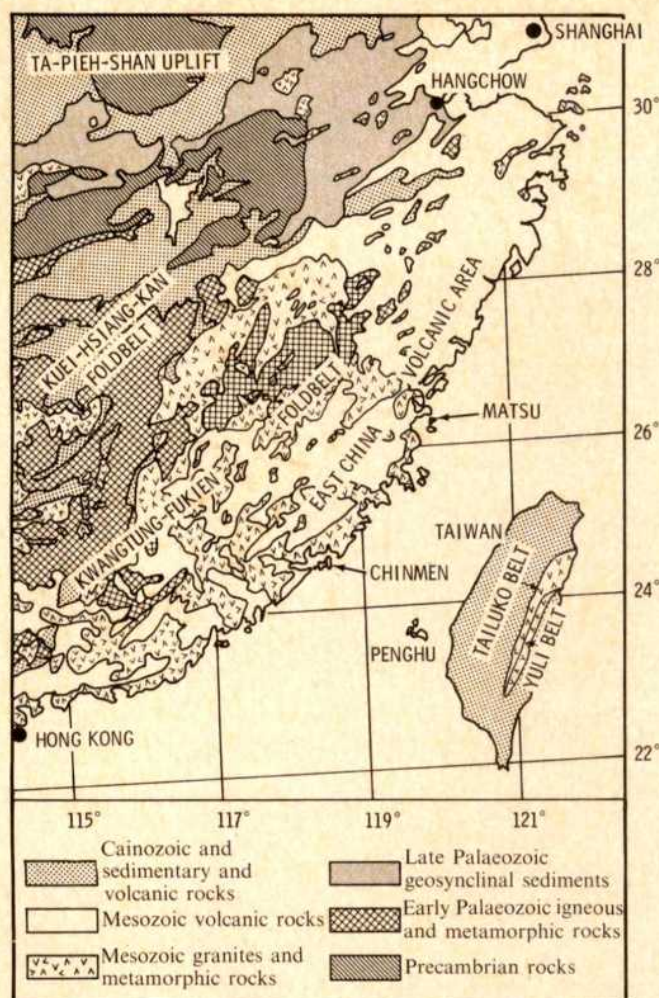

FIG. 1 Generalised geological map of southeastern China and Taiwan. Source, refs 11 and 28.

reversal time scale, they show that from 110 to 85 Myr there was a pulse of very rapid spreading in the central and south Atlantic and throughout the Pacific (up to 18 cm yr⁻¹ along the Phoenix-Pacific spreading centre).

With a rigid plate assumption, rapid spreading corresponds to rapid subduction and consumption of oceanic plate materials beneath the surrounding continents. (This statement is not strictly true, for subduction may be beneath oceanic but not continental lithosphere, for example, in the western Pacific. However, from an analysis of tectonic activities along the Pacific margins during the Mesozoic time, this statement is generally true.) If andesitic or granitic magmas of continental margins and island arcs were derived from the under-thrust lithosphere or had any genetical relationship with the subduction, one may anticipate a correlation between spreading rate and the intensity of orogeny and associated thermal episodes (andesitic volcanism, batholithic intrusion and metamorphism). Indeed, Larsen and Pitman¹ related the pulse of rapid spreading from 110 to 85 Myr BP to episodes of circum-Pacific intrusive and extrusive activity and orogenic movement during this period.

Here, I report a new set of age data on some granitic batholiths of southeast China. I shall show that these new data support the postulate of Larsen and Pitman.

The geotectonic element of which the southeast China coastal region is a part was named 'Cathaysia' by Grabau³. It includes the South China Basin, Taiwan, the Yellow Sea and Japan, and it was suggested to be an 'old land' of Precambrian age. This 'old land' supplied detritus to a Cathaysian geosyncline to the northwest, only to disappear as the

geosyncline later migrated southeastward. But Hsieh⁴ rejected Grabau's concept of an 'old land' and suggested that the bulk of the Kuei-Hsiang-Kan and the Kwangtung-Fukien Foldbelts (Fig. 1) are younger Caledonian, and postulated a Hercynian foldbelt north of Canton (not shown in Fig. 1, but located about 50 km northwest of Hong Kong) and a larger Mesozoic foldbelt along the coastal region of southeast China.

The basement rocks of southeast China are principally metamorphic rocks of various facies associated with intrusive granites. Their ages are not known. Toward the coastal areas, volcanic rocks, also associated with intrusive rocks, comprise the widespread East China Volcanic Area. It has been speculated that they are of Jurassic-Cretaceous age. During the Mesozoic Yenshan Orogeny in China (whose early phase corresponding to the Nevadan Orogeny of the western United States) folding and faulting of sedimentary rocks were accompanied by volcanism and intrusion. Extensive Mesozoic granites were thus developed throughout the southeastern part of China. The period of Yenshan Orogeny includes the most important metallogenetic epochs of the whole of China⁵.

Dating the rocks

Rocks collected from two offshore islands (Chinmen and Matsu) were dated by the Rb-Sr method. All granitic rocks from Chinmen and Matsu, including granitic gneisses and biotite-hornblende gneisses, yielded mineral isochron ages of 93 to 109 Myr (Table 1). A late pegmatitic dike (K-4), which intruded a granitic body (K-3), was dated at 90 Myr. The initial ⁸⁷Sr/⁸⁶Sr ratios of these rocks vary with the Rb/Sr ratios of the individual rocks from 0.706 to 0.716. Dioritic and gabbroic rocks from Matsu yield similar ages (94.1 to 97.5 Myr), with a very narrow range of initial ratios of about 0.7065 to 0.70695. In addition, a primary age of 165 Myr, with an initial ⁸⁷Sr/⁸⁶Sr = 0.7055, was obtained from the whole rock data for granitic rocks, implying either that these rocks may be genetically related and of mantle origin with limited crustal contamination or that the original sedimentary sources for the granitic gneisses were Sr isotopically homogenised about 165 Myr ago.

The whole rock data for the mafic rocks from Matsu (diorites, gabbro and spessartite) are more scattered and

TABLE 1 Mineral and whole-rock isochron ages and initial ⁸⁷Sr/⁸⁶Sr ratios of some igneous rocks from Southeastern China

Sample No.	Locality	Rock type	Age (Myr)	(⁸⁷ Sr/ ⁸⁶ Sr) ₀
K-1	Chinmen	granite gneiss	95 ± 2*	0.7084 ± 1*
K-2	"	bio-hb gneiss	96.7	0.7060
K-3†	"	granite gneiss	109 ± 7	0.7079 ± 5

Whole-rock§	Chinmen & Matsu	granites	165 ± 13	0.7055 ± 2

* Ages were calculated by the York method³⁰ using the decay constant of ⁸⁷Rb = 1.39 × 10⁻¹¹ yr⁻¹. Uncertainties for both ages and initial ⁸⁷Sr/⁸⁶Sr ratios are at 2σ level except for K-2 which is a two-point isochron. Uncertainties of initial ratios correspond to the last figures.

† K-3 was intruded by K-4 pegmatite dike.

‡ Initial ⁸⁷Sr/⁸⁶Sr ratios corrected for radiogenic ⁸⁷Sr growth in the assumed time interval of 95 Myr.

§ Whole-rock isochron was constructed using the data of K-1, K-2, K-3, K-5, K-7, M-06 and MPK.

TABLE 2 Mesozoic thermal events in circum-Pacific areas (based on radiometric dates)

Area*	Description and comment	References
Alaska-Aleutian Range	Three discrete episodes of intrusions are found: (1) early to middle Jurassic (176-154 Myr), (2) late Cretaceous and early Tertiary (83-58 Myr), (3) Middle Tertiary (38-26 Myr). All ages are K-Ar mineral dates.	14
Coast Range, British Columbia	Orogenic pulses took place from Proterozoic to late Tertiary. K-Ar dates suggest that plutonic emplacement and later uplift were most vigorous and widespread in Cretaceous and Tertiary.	15
Sierra Nevada	K-Ar and Rb-Sr data show that intrusion began in late Triassic (210 Myr) and ended in late Cretaceous (80 Myr). Emplacement of granites accomplished in five major epochs, regularly separated by 30 Myr intervals. Magmas were derived from the upper mantle or lower crust with some sialic contamination.	7, 16, 17
Franciscan Formation	K-Ar dates span from 150 to 70 Myr. Three major metamorphic events: (1) 150 Myr, (2) 90-110 Myr, (3) 70 Myr. These events are correlated with intrusive epochs in the batholith belt (example, Sierra Nevada).	9
SW United States	K-Ar dates indicate two broad patterns which culminate in (1) the Jurassic (160-130 Myr) and (2) the mid- to late Cretaceous (105-75 Myr). Essentially coeval with Franciscan and Batholith belt activities.	8
Baja California	U-Pb age = 96-118 Myr. Rb-Sr data indicate a mantle source for the Peninsular Range batholith.	18
Northern Chile	K-Ar biotite ages indicate four episodes of granitic intrusion: (1) lower Jurassic (182-190 Myr); (2) middle Cretaceous (87-107 Myr); (3) lower Palaeocene (60-67 Myr); (4) upper Eocene (40-43 Myr). Intrusive foci migrated eastwards.	19
Southern Chile	K-Ar and Rb-Sr ages indicate three major episodes of intrusion into the basement complex of Palaeozoic age: (1) 164-126 Myr; (2) 106-80 Myr; (3) 53-11 Myr. (Original Rb-Sr ages were recalculated using Rb decay constant = $1.39 \times 10^{-11} \text{ yr}^{-1}$).	20
Antarctica	Granites and granodiorites from the peninsular region of western Antarctica show a pattern of Mesozoic igneous activity similar to that of South Andes region. Rb-Sr ages clustered around 96-109 Myr.	21, 22
New Zealand	Radiometric dates for intrusive and metamorphic rocks on both sides of the Median Tectonic Line of the South Island cluster in the interval 95-120 Myr. The timing of the Cretaceous orogeny and paired metamorphism in New Zealand is similar to that in Japan.	23
Southeast China	Rb-Sr W. R. isochron age of 165 Myr suggests a primary thermal event for the Chinmen granites. Mineral isochron ages, which cluster in the interval 94-109 Myr, correspond to a secondary thermal event for the Chinmen granites and a primary intrusive event for the Matsu diorites and gabbros.	This paper
Taiwan	K-Ar age of 86 Myr for a muscovite from a quartz diorite which intruded agneissic rock in the Tailuko Belt (low P/T), immediately west of the Yuli Belt (high P/T type). The time of intrusion corresponds to that of the Nanao Orogeny in Taiwan and an episode of the Yenshan Orogeny in China.	12
SE Asia	Granites northeast of Gulf of Thailand are mainly Triassic or older. Widespread thermal events including granitic emplacement took place during Cretaceous to Tertiary. In Indonesia, granites from the Lassi Mass and the Lampong Mass of Sumatra and from offshore areas north of Java were dated at about 100 Myr.	24, 29
Japan	K-Ar dates indicate that most intrusion took place in early Cretaceous to early Tertiary (90%), and weakly continued to late Tertiary. Paired metamorphism occurred during middle Cretaceous time.	25, 26
South Korea	Rb-Sr data indicate that a thermal event (180 Myr) homogenised Sr isotopic compositions of mineral phases in a Precambrian rock. Whole rock data of five granitic rocks from the southeast coastal region yield an age of about 100 Myr.	27

* Areas arranged clockwise around the Pacific.

do not form any linear isochron relationship (details to be published by B. J., P. Y. Chen and T. P. Yen). Their initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of 0.7065 to 0.70695, derived from mineral isochrons, suggest a possible mantle origin with some crustal contamination. It is quite certain, however, that the source materials for the Chinmen and Matsu granites were not solely Rb-rich crustal rocks of much older ages, such as the Precambrian strata of the Ta-Pieh-Shan Uplift.

In summary, the granitic rocks probably record a primary (165 Myr) and a secondary (about 100 Myr) thermal episode, while the unmetamorphosed diorites and gabbro from Matsu register only a time of intrusion also at about 100 Myr. The time interval of 90 to 109 Myr BP embraces an outstanding episode of the Mesozoic Yenshan Orogeny in China.

It is of great interest to see how the rapid seafloor spreading during the time interval of 110-85 Myr BP correlates with supposedly consequential dynamic events on the continents, especially in the circum-Pacific areas. Gilluly⁶ stated "The Middle Cretaceous was the time of emplacement of by far the greatest plutons of Phanerozoic time in the whole

belt extending from Alaska to Baja California. The batholiths of the Peninsular Range, the Sierra Nevada, many of the Coast Range plutons of California, the Idaho Batholith and many of its satellites in eastern Oregon and northern Idaho all belong to this episode. The plutons of northeastern Washington are outliers of the great Coast Range batholith of British Columbia." To supplement the evidence cited by Larsen and Pitman, I have collected some more supporting evidence shown in Table 2. Not all the age data in Table 2 explicitly indicates a strong peak during the 85 to 110 Myr interval in the age distribution pattern. This is easily understood if factors such as sampling bias and rates of uplift and subsequent erosion which exposed the intrusive rocks are considered. Furthermore, even during a period of rapid spreading, the rates of lithosphere consumption and accompanying igneous activities will not necessarily be increased uniformly around the Pacific margins. The possibility of a fortuitous coincidence between the fast spreading indicated by the magnetic anomaly time scale and the magmatic episodes should not be overlooked. Perhaps Larsen and Pitman's time scale is premature and may be changed after

more detailed study. Similar doubts about such a correlation and about the regular periodic magmatic events proposed by Evernden and Kistler⁷ for the Sierra Nevada were raised by Armstrong and Suppe⁸. Nevertheless, the present data for China are consistent with the interpretation of Larsen and Pitman.

Metamorphism with intrusion

Finally, I would like to call attention to the coeval occurrence of paired metamorphism and intrusion on both sides of the Pacific during the Mesozoic. On the east side the Franciscan terrain is parallel to and west of the batholith belt of California. The metamorphism of the Franciscan Formation occurred from 150 to 70 Myr BP, a time span which is essentially contemporary with the times of most extensive magmatism in the batholith belt⁹.

On the west side of the Pacific, there are the classical examples of paired metamorphic belts in Japan¹⁰, and the Yuli Belt of high pressure/low temperature glaucophane schist in Taiwan, about 170 miles east of Chinmen and Matsu (Fig. 1). Since no systematic radiometric dating has been done on these metamorphic rocks, a direct correlation is not possible. Based on field relationships, however, the metamorphism was thought to occur in late Mesozoic¹¹. Moreover, as shown in Table 2 a single K-Ar date of 86 Myr¹² was reported for muscovite from a quartz diorite which intruded a gneissic rock of the Tailuko Belt, with which the Yuli Belt is in fault contact. Thus the high-pressure type of metamorphism in Taiwan may be coeval and tectonically paired with the low-pressure type of metamorphism and plutonic intrusion in southeast China. This mirrors the situation in California. Yen¹¹ proposed that the Tailuko (low P/T type) and the Yuli belts (high P/T type) in eastern Taiwan (Fig. 1) formed the paired metamorphic belts which are now in direct fault contact. If the so-called arc-trench gap¹³ was ever present between these two metamorphic belts, it would require a great amount of crustal displacement to bring these two together. Perhaps a more logical way is to pair the Yuli belt with the batholiths of southeastern China. This specific problem will be discussed elsewhere (B. J., P. Y. Chen, and T. P. Yen, to be published).

I thank Dr M. Bass for his valuable comments and the National Research Council for providing a post-doctoral research associateship held at the NASA Johnson Space Center.

Free precession of neutron stars

David Pines

Physics Department, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

Jacob Shaham

Racah Institute of Physics, Hebrew University, Jerusalem, Israel

Wobble in pulsars can provide a clue to the structure and properties of the associated neutron stars.

DETECTION of free precession represents one of the most promising methods of determining both the mass and internal structure of a neutron star. The free precession frequency differs by some three (or more) orders of magnitude, depending on whether the star possesses a solid or a liquid core¹. Thus if one attributes the 35 d period of the high-low X-ray cycle observed for the compact X-ray source Her X-1 (ref. 2) to free precession of the neutron star Her X-1 (refs 3, 4) then from the magnitude of that period alone one can conclude that Her X-1 possesses a solid inner core

(of hyperons or neutrons)⁴. Here we examine ways of exciting and maintaining such precession, as well as mechanisms which act to damp it. This problem has been considered earlier by Goldreich⁵ and by Henriksen *et al.*⁶, whose starting assumptions and conclusions differ somewhat from ours. We conclude that crust-liquid coupling is probably the principal source of wobble damping and that for pulsars wobble excitation is more easily accomplished in a comparatively young, rapidly rotating neutron star. For the Crab and Vela pulsars we find that wobble damping is comparatively ineffective, so that a moderately effective pumping mechanism suffices to excite stellar wobble to an amplitude ($\sim 6^\circ$ to 15°) limited only by the maximum storage of angular elastic energy in the solid crust (or core) of the star.

Analogy with terrestrial wobble

To put the problem of exciting stellar wobble in a terrestrial perspective, we note first that 80 years after the discovery of the free precession of the Earth by Chandler in 1891, the mechanism which is responsible for exciting this Chandler wobble remains in doubt. It is now generally believed that the dissipation in shallow oceans of energy associated with polar tidal motions is sufficiently great that, left to its own devices, the Chandler wobble would damp in less than 100 yr (ref. 7). Yet after almost 100 yr of observation, the amplitude of the wobble (~ 6 m or 10^{-6} rad) remains essentially unchanged; a mechanism to pump the Chandler wobble is clearly required.

Three of the various suggested terrestrial pumping mechanisms are of particular interest to the astrophysicist interested in pumping the wobble of a neutron star: (1) random pumping by earthquakes^{8,9}; (2) random pumping by the core-mantle interaction¹⁰; (3) resonant pumping by earthquakes as a result of in-phase release of angular elastic energy, triggered by the Chandler wobble itself¹¹.

The first mechanism is too inefficient to maintain the Chandler wobble at its present amplitude¹²; its analogue may, however, be operative for a comparatively young neutron star with a solid core (the Vela pulsar?). To the extent that the interpretation of the giant Vela spin ups as produced by corequakes¹³ is correct, such corequakes could excite a substantial stellar wobble through the discontinuous jumps in the centre of nutation they bring about.

An analogue of the second mechanism—random angular momentum transfers between the core and crust of a neutron star—could well act to maintain the precession of a neutron star with a liquid interior (the Crab pulsar?). We lack, however, any physical picture for what might be causing such transfers (which would be reflected as frequency jumps analogous to the changes in the length of the day observed for the Earth); moreover, because of its randomness, such a mechanism is comparatively inefficient, so that pumping a large amplitude stellar wobble in this fashion may be difficult.

An analogue of the resonant pumping mechanism might operate in a neutron star like Her X-1, for which it has been suggested⁴ that the free precessional motion of the star acts to regulate the accretion of matter to the stellar surface. If corequakes in the solid core of Her X-1 are triggered by such accretion (and crustquakes could provide the catalyst needed to bring this about), we would then have a quite efficient self-regulating system: on the one hand, stellar wobble regulates the accretion of matter to the stellar surface (which we see on Earth as a high X-ray state); on the other hand, corequakes triggered by that accretion act to maintain the core wobble. Although the direct detection of such corequakes would be difficult (even in the case of a frequency jump, $\Delta\Omega/\Omega$, as large as 10^{-6}) such quakes could be indirectly detected through the changes in amplitudes of the stellar wobble they produce and may indeed have already been detected. A sizeable jump in the amplitude of the stellar wobble would alter the pattern of the high-low X-ray states, so that one would observe the high X-ray state for a greater (or smaller) number of days within the ~ 35 d overall cycle. Since such shifts in the high-low X-ray cycle have been frequently seen, it is tempting to attribute them to shifts in the amplitude of the stellar wobble; more work is, however, needed before such an interpretation can be taken seriously.

Pulsar mechanism

In a pulsar there is an additional mechanism which might be responsible for exciting stellar wobble—the radiation torque associated with the pulsar magnetic field. Goldreich⁴

has examined the change in nutation amplitude brought about by the electromagnetic torque associated with magnetic dipole radiation; he finds that free nutation grows or damps on the slowing down time scale ($T \sim 2,500$ yr for the Crab pulsar) depending on whether the angle, χ , between the magnetic axis and elastic reference axis exceeds or is less than $\sim 55^\circ$; the rate of growth is, however, proportional to the amplitude to nutation, so that it seems difficult to achieve an appreciable nutation amplitude in times which are not long compared to T . We have examined the problem from a somewhat different point of view; in considering the influence of a torque which acts perpendicular to the reference axis, n_0 , we found that the effect of such a torque depends on whether it is fixed in the star or adjusts to the reference plane formed by the angular momentum L and the reference axis, n_0 (ref. 14). In the former case, the maximum angular amplitude of the stellar wobble is $\sim 1/\Omega\tau_{\text{el}}$, where (L/τ_{el}) is the magnitude of the external torque; in the latter case, the wobble amplitude increases linearly with time, with a growth rate independent of its amplitude; the maximum amplitude is then determined by either the elastic properties of the stellar crust or by crust-core coupling which may act to damp the wobble motion. We found that in order to achieve nutation amplitudes sufficiently large to be observable (either directly or through microquakes induced by the corresponding growth in the angular part of the elastic energy stored in the crust), we require a torque fixed in the reference plane, L/τ_{el} , which is large compared to the slowing down torque, L/T .

A possible candidate for such a torque is a component of the stellar field, B_0 , which is sensitive to Ω and the actual figure axis; such a field, instead of being fixed in the star, adjusts to the reference plane and gives rise to an effective torque in the star (as viewed by a corotating observer)

$$\mathbf{N}_{\text{eff}} = -\epsilon_B I_0 (\boldsymbol{\Omega} \times \hat{\mathbf{B}}_0) (\boldsymbol{\Omega} \cdot \hat{\mathbf{B}}_0) \quad (1)$$

where ϵ_B is the 'magnetic' stellar oblateness

$$\epsilon_B = \frac{\alpha B_0^2 R^3}{4(A+B)} \quad (2)$$

and $\hat{\mathbf{B}}_0$ is a unit vector in the direction B_0 . In equation (2) α is of order unity, whereas A and B measure the gravitational and elastic energy stored in the star. (For a self-gravitating incompressible sphere, $A \simeq (3/25) GM^2/R$, and $B = (57/50) \mu V_c$ for a star of radius R with solid crustal (or core) material of volume V_c and shear modulus μ .) The torque (1) is independent of the wobble amplitude for small amplitudes; it is of order of magnitude $10^{30} \sin 2\chi$ for typical stellar fields and can, in principle, be several orders of magnitude larger than the slowing down torque; it would, however, be observable only through its influence on the wobble amplitude, which would, under these circumstances, be sufficiently large both to bring about microquakes in the star and to be directly detectable. The question then reduces to the difficult one of whether currents in the core can produce and maintain a magnetic field of this character (tied to Ω and to the shape of the crust).

Since it is sensitive to both Ω and the shape of the crust, such a field configuration must be able to slip with respect to the crust. We must therefore postulate the existence of a current sheath at the crust-core interface, which acts to decouple the field in question from the 'radiation' fields within the crust. Such screening currents are likely to appear in the star at the time the crust freezes and we are now studying ways by which this comes about.

We further note that the fields in question need not be dipolar and could well be turbulent; all that is required is that the crustal strains induced by them follow the reference plane. Under these circumstances, equations (1) and (2)

should be replaced by the suitably generalised tensor relations.

Prospects for observing such effects

Assuming that mechanisms for exciting a stellar wobble exist, the amplitude of that wobble will depend, of course, on the extent to which it is damped; here, the situation looks rather favourable for would-be wobble observers. First, in view of the likely homogeneity and sharpness of the stellar surface, the latter a consequence of the strong stellar magnetic field¹⁵, it is reasonable to conclude that no shallow oceans exist on the surface of a neutron star, so that the mechanism responsible for damping the Earth's wobble will be absent. Second, the crustal temperature of a neutron star is exceedingly low compared to its melting temperature ($T/T_m \lesssim 10^{-3}$), so that the only creep mechanism operation is the so-called logarithmic, or low temperature, creep; the time scales for the resulting plastic flow are therefore long compared to the slowing down time, T (ref. 16). Indeed, to the extent that pulsar spindown increases the elastic energy content of the crust, T provides an upper limit to the extent to which plastic flow in the crust can act to damp pulsar wobble.

Crust-liquid coupling is probably the principal source of wobble damping but this too is comparatively ineffective. From the postglitch behaviour of the Crab and Vela pulsars one knows that the time, τ , required for the crust and superfluid neutron liquid to come into equilibrium is of the order of days to years^{17,18}; such coupling gives rise to a damping time for the pulsar wobble which is far longer, being¹⁹

$$\tau_w = \frac{\Omega}{\Omega_w} \tau = \frac{2}{3} \left(\frac{A+B}{B} \right) \frac{\tau}{\epsilon_0} \quad (3)$$

on making use of the expression²⁰,

$$(\Omega_w/\Omega) = \frac{2}{3}(B/A + B)\epsilon_0 \quad (4)$$

for the free precession frequency, Ω_w . For the Crab pulsar, assuming it to have a liquid interior, $(\Omega_w/\Omega) \lesssim 10^{-7}$, so that $\tau_w \gtrsim 3 \times 10^4$ yr, at least an order of magnitude greater than the slowing down time T_{Crab} ($\sim 2,500$ yr); for the Vela pulsar, the wobble damping time is shorter than T_{Vela} ($\sim 24,000$ yr), being ~ 500 yr if the Vela pulsar is assumed to possess a solid core with $\epsilon_0 \sim 3 \times 10^{-3}$.

Given such long wobble damping times, it is reasonable to expect large amplitude stellar wobble for those neutron stars for which the effective magnitude of the exciting torque, L/τ , exceeds the slowing down torque, L/T . In such cases, the amplitude of the stellar wobble is likely limited by the maximum storage of angular elastic energy ($\propto \theta_0^2$ where θ_0 is the angular wobble amplitude) in the solid crust (or core) of the star. For the Crab pulsar, we have previously estimated that starquakes will limit the maximum wobble amplitude for a star of mass $0.25M_\odot$ to some 5° if the angular contribution to the elastic energy is comparatively small, 15° if this contribution dominates the elastic energy¹⁴. For a pulsar with a solid core, comparable wobble amplitudes may be expected; for example, if $\sigma_c/\mu\epsilon_0 \sim 1/7$, the limit on the wobble amplitude is $\sim 6^\circ$.

In their consideration of this problem, Henriksen *et al.*⁶ have assumed that the Goldreich mechanism, in which B_0 is constant in the star, is operative, and have calculated the maximum wobble amplitude for the following two cases:

(1) Stabilisation of the wobble amplitude either by internal friction in the crust or by core-crust coupling.

(2) Wobble at the elastic limit, followed by plastic flow. The estimates we have given above suggest that case (1) is probably not realised in practice; the very low temperature of the crust seems to preclude an effective internal

friction mechanism, whereas for the Crab pulsar, at least, the damping time associated with core-crust coupling is long compared to the excitation time, T , assumed by Henriksen *et al.*, so that core-crust coupling could not act to stabilise the wobble amplitude. Case (2) also does not seem realisable in practice. If only the Goldreich excitation mechanism is operative, examination of the rate of change of the oblateness and angular mismatch terms in the elastic energy shows that the oblateness mismatch contribution will grow at a faster rate than that associated with the wobble amplitude; as a result the wobble amplitude could never be large enough to induce either plastic flow or a microquake. Finally, should it reach such a critical size, we would argue that because the crust is so cold, a series of microquakes are more likely to ensue than plastic flow.

We conclude by emphasising that proposed mass and structure assignments for the Crab and Vela pulsars put definite limits on the precession frequencies one would expect to observe. Thus, for the Vela pulsar, assuming it to be sufficiently massive to possess a solid core, the corequake interpretation¹³ of its giant speedups requires an $\epsilon_0 \gtrsim 10^{-3}$; taking $B \gtrsim A$, we are led to a wobble period

$$P_w \lesssim 100 \text{ s (Vela pulsar)} \quad (5)$$

For the Crab pulsar, assuming it to have a liquid interior and a mass $> 0.3M_\odot$, the wobble period is

$$P_w \gtrsim 16 \text{ h (liquid core Crab pulsar)} \quad (6)$$

On the other hand, assuming the stellar structure of the Crab pulsar were such that it had a solid core and $(I_w/I) \sim 0.9$, one would expect that $\epsilon_0 > 10^{-3}$ and $B > A/10$, in which case

$$P_w \lesssim 5 \text{ min (solid core Crab pulsar)} \quad (7)$$

Observation of a Crab pulsar wobble could thus provide a decisive determination of its stellar structure.

Relative positions of the 'repetitive', 'unique' and poly(A) fragments of mRNA

Dino Dina, Isaura Meza & Marco Crippa

Department of Animal Biology, 154, Route de Malagnou, Geneva

The mRNA molecules from Xenopus laevis embryos represent polyribonucleotide chains of heterogeneous size transcribed from unique DNA sequences, each carrying a poly(A) stretch at the 3' terminus and at the 5' terminus, a fragment of 50 to 60 nucleotides transcribed from repeated DNA sequences.

We have previously discussed the existence of sequence heterogeneity in the mRNA molecules isolated from *Xenopus* embryos¹. On the basis of hybridisation kinetics, we concluded that each mRNA molecule was composed of a main fragment transcribed from unique DNA, with a covalently-linked smaller fragment transcribed from homologous repeated DNA sequences². It was, however, impossible to draw any conclusions about the positions that such fragments could have within each mRNA molecule.

As very similar 'repetitive' fragments seemed to be linked to different unique parts, we decided to investigate in detail the uniformity of their size and location in each mRNA molecule, also with respect to the poly(A) stretches known to be present on the majority of mRNAs.

We here present data showing that the 'repetitive' fragment is located at the 5' end of the mRNA and is 50–60 nucleotides long. We have also observed that most of the mRNAs in these embryos contain a stretch of poly(A) which is heterogeneous in size and is located at the 3' end of the molecule.

Isolation of mRNA and characterisation of the poly(A) fragment

Tritium-labelled mRNA was isolated from polyribosomes of dissociated *Xenopus* neurulae following procedures already described^{1,3}. The possible degradation of the mRNAs during extraction was already discussed and ruled out in a previous report¹ by coextracting the embryos with purified globin mRNA. Several controls also showed that significant amounts of labelled newly synthesised rRNA did not contaminate our mRNA preparation. Finally, the possibility that the ³H-uridine counts associated with the polysomes could represent cosedimenting HnRNA molecules leaked out from the nuclei is extremely unlikely in view of the fact that after only 15 min labelling, although a significant amount of newly synthesised RNA was observable, practically no radioactivity could be detected on the polysomes. It was only after longer labelling times (30 min or more) that newly synthesised RNA molecules became associated with the polysomes.

The newly synthesised mRNA sedimented on sucrose gradients as a broad peak of 12S, was very heterogeneous on acrylamide gel electrophoresis and it did not bind to Millipore

filters in 0.5 M KCl (ref. 1). Binding to nitrocellulose filters under these conditions has been reported for poly(A) containing RNAs (ref. 4) and practically all the eukaryotic mRNA investigated (except histone mRNA)⁵ have been found to contain a poly(A) stretch.

As we could have selected for molecules not containing poly(A) by our phenol extraction procedure performed in 0.1 M acetate pH 5.0 (ref. 1), we decided to re-investigate the properties of the mRNA purified from embryos labelled with ³H-adenine. The RNA was phenol-extracted in low salt and neutral pH. In these conditions, more than 90% of the radioactivity present on the polysomes is recovered after extraction and at least 60–70% of the counts are eventually found in the 12S peak on sucrose gradients. The rest of the labelled RNA sediments faster and was usually discarded because of its contamination with 18 and 28S rRNA. Millipore filters retained 25–35% of the RNA purified in this way.

To investigate the content and properties of the poly(A) associated with these RNA molecules, embryos were dissociated and labelled with ³H-adenine for 30 min or 4 h (Fig. 1). The RNA was extracted from the polysomes and digested for 30 min with RNase A and T₁. The amount of RNase-resistant material ranged between 4% and 7% of the total counts incorporated into polysomal RNA. Eighty per cent of the counts resistant to RNase A + T₁ became TCA soluble when digested with a mixture of ribonucleases T₁ + T₂, known to digest poly(A) stretches⁶. Acrylamide gel electrophoresis of the RNase-resistant material shows two distinct patterns; at 30 min (Fig. 1a) the poly(A) is distributed as the predominant peak which migrates slower than the 4S and 5S markers. The average length of the fragments in this peak is more than 120 nucleotides. The counts found consistently on both sides of the main peak demonstrate some degree of heterogeneity in the size of the poly(A) piece. At 4 h (Fig. 1b) a small amount of label is found in the 120 nucleotide peak as the poly(A) pieces are more heterogeneous in size and are distributed towards the lighter region of the

TABLE 1 Elution pattern of RNA and single stranded DNA from the HAP column before hybridisation

Phosphate molarity	% RNA eluted	% DNA eluted
0.12 M	70	100
0.14 M	13	—
0.16 M	13	—
0.20 M	—	—
0.50 M	4	—

500 µg of DNA were denatured in 0.12 M phosphate buffer for 15' at 100°C; during the cooling in ice 5,000 c.p.m. of neurula mRNA were added. The sample was then fractionated on a HAP column at 66°C.

Fig. 1 Determination of poly(A) size. One thousand embryos were dissociated under the usual conditions¹. Half were then incubated in the presence of $100 \mu\text{Ci ml}^{-1}$ of ^3H -adenine for 30 min (a) while the rest were incubated under the same conditions for 4 h (b). At the end of the incubation the embryos were homogenised in sucrose-TKM buffer (35 mM Tris pH 7.4, 10 mM MgCl_2 , 70 mM KCl, 0.25 M sucrose, $7.5 \mu\text{g ml}^{-1}$ PVS and 0.5% DOC) and the polysomes prepared by sedimentation on 15–50% sucrose gradients. After extraction of the polysomes with phenol saturated with 10 mM Tris pH 7.5 and chloroform, the two samples were ethanol precipitated. The RNA was resuspended in 10 mM Tris pH 7.5, 0.2 M NaCl and incubated with $20 \mu\text{g ml}^{-1}$ of RNase A and 10 units ml^{-1} of T_1 for 30 min at 30°C . After ethanol precipitation using 1.0 absorbance unit of *E. coli* soluble RNA as carrier, the RNA was resuspended in 0.5% SDS and electrophoresed in 10% SDS acrylamide gels for 3 h at 5 mA per gel. The gels were cut into 2 mm slices, solubilised and counted. The top of the gel corresponds to the left side in the figures.

gel. Most of these fragments are lighter than the 4S marker and therefore not long enough to retain a whole RNA molecule when passed through Millipore filters. This could explain the low percentage of binding to filters that we obtain with the purified RNA.

We conclude that at short labelling times the mRNA molecules that reach the cytoplasm carry a rather long and homogeneous fragment of poly(A). When longer incubations are performed, the size of the poly(A) fragment decreases and mRNA molecules with shorter heterogeneous poly(A) fragments are detected, which seem to accumulate on the polysomes. Similar observations, which substantiate the cytoplasmic accumulation of mRNA-bearing short poly(A) stretches, have been made using the drug 3-deoxyadenosine³, known to inhibit the synthesis of poly(A) (ref. 7). There are data showing that the cytoplasmic poly(A) has a very wide distribution of sizes⁸ and that poly(A) is metabolised in the cytoplasm^{3,9,10}.

The presence of a poly(A) fragment on each mRNA molecule has also been studied, indirectly, by the use of 3-deoxyadenosine. A batch of dissociated embryos was treated for 30 min before the addition of radioactivity with $50 \mu\text{g ml}^{-1}$ of 3-deoxyadenosine. The sample was then incubated in parallel with an untreated control for 2 h in the presence of $100 \mu\text{Ci ml}^{-1}$ of ^3H -adenine. The embryos were homogenised and the polysomes prepared on sucrose gradients. Only 20% of the counts in the control polysomes were found in the 3-deoxyadenosine-treated sample. These results, obtained after long treatment with 3-deoxyadenosine, cannot be due to a specific decrease in RNA synthesis caused by drug damage to the embryos, since embryos kept as long as 2 h in $50 \mu\text{g ml}^{-1}$ of 3-deoxyadenosine and pulse-labelled with ^3H -uridine for 15 min at different times during this period showed the same amount of incorporation as the controls kept in normal saline solution. Therefore, the ap-

pearance of most of the mRNA on the polysomes must depend on the addition of poly(A) to the messenger precursor.

The poly(A) piece has been reported to be localised at the 3' end of the RNA molecule in many of the messages isolated¹¹; so we decided to determine its exact location in our system, to present a more accurate picture of the possible structure of the mRNA molecules.

For this purpose, the isolated poly(A) piece, obtained as indicated in Fig. 1, was subjected to alkaline hydrolysis in conditions that lead to at least 95% hydrolysis of the polymer to the 2', 3'-monoesters¹². The hydrolysate was then examined by paper chromatography using cold adenosine and synthetic poly(A) (also digested with alkali) as markers for nucleosides and mononucleotides. We found the radioactivity located mainly in two spots (Fig. 2). As expected, the highest counts were found in the region corresponding to mononucleotides and approximately 1% of the total counts were found in the region coinciding with the adenosine marker.

Fig. 2 Distribution of radioactivity in the alkaline hydrolysate of the poly(A) piece. The isolated poly(A) piece, obtained from embryos labelled for 2 h with ^3H -adenine, and synthetic poly(A) (Miles Laboratories, U.S.A.) were hydrolysed for 40 min at 100°C in 0.05M KOH. After hydrolysis the samples were neutralised, spotted on Whatman 3MM paper and subjected to descending chromatography in 1 M ammonium acetate pH 7.5–95% ethanol (30:75 v/v) for 10 h. A parallel paper strip containing cold adenosine was run at the same time. Paper strips were cut into 2 cm squares after exposing the spots in ultraviolet light. The paper pieces were counted in Triton-fluor mixture after digestion with 0.1M NaOH for 2 h and neutralisation with acetic acid. ●, poly(A) hydrolysate from the embryo mRNA; ○, hydrolysate from synthetic poly(A).

Fig. 3 Size of the isolated 'repetitive' fragment. The RNA (3,000 c.p.m.), obtained as outlined in the text, was resuspended in 0.5% SDS denatured at 100° C and electrophoresed for 3 h on 10% acrylamide gels²² tRNA and 5S RNA were used as markers. Gels were scanned in a Gilford densitometer at 260 nm and sliced into 2 mm pieces. After solubilisation in Soluene, the samples were counted for radioactivity.

The conditions used for hydrolysis do not produce significant dephosphorylation of nucleotides¹² so the nucleoside found should correspond to the 3'-OH terminal nucleotide in the poly(A) stretch. Since the enzymatic treatment does not produce a free 3'-OH end in the nuclease-resistant piece, the free OH group should correspond to the 3' end in the RNA molecule and therefore the poly(A) fragment should be localised at this end. The ratio of labelled nucleotides to nucleosides provides an average value of 75-100 nucleotides per each terminal adenosine residue in the poly(A) stretches. This value is in good agreement with the estimation from gel electrophoresis for the size of the poly(A) fragments from embryos labelled during 2 h (ref. 3).

Isolation of the 'repetitive' RNA fragment

As already mentioned, each mRNA molecule is internally heterogeneous: a part of it is transcribed from homologous repeated DNA sequences while the other is transcribed from the unique part of the genome. These two parts, called 'repetitive' and 'unique' fragments, are covalently linked and therefore present on the same mRNA molecule.

The arrangement of the sequences that we have proposed leads to two predictions: first, if each molecule carries a very similar or even identical 'repetitive' fragment, the size of the isolated part should be somewhat homogeneous. Moreover, the isolated and purified 'repetitive' stretch should rehybridise in the presence of DNA in excess, with its reiterated DNA complements reassociating completely before C_{ot} 100 (see ref. 1).

To isolate the fast hybridising part of the mRNA 120,000 c.p.m. of purified total mRNA was incubated with 30 mg of sonicated denatured DNA to C_{ot} 100. The conditions used were 0.12 M phosphate buffer and 68° C. At the end of the incubation an aliquot was withdrawn and treated with RNase (5 μ g ml⁻¹ RNase A, 30 min at 30° C). The sample was then diluted with 0.12 M phosphate buffer containing 1 M NaCl and loaded on a column of hydroxylapatite (HAP) at 66° C (ref. 13). The ratio of DNA to HAP was about 10 absorbance units of DNA (measured on native DNA before the initial melting) per ml packed HAP. The column was washed with 0.12 M phosphate—1 M NaCl until no

more DNA or radioactivity could be eluted. This step, as shown in Table 1, allows the recovery of about 70% of the RNA counts in the control, monitored before annealing. The column was then washed with increasing concentrations of phosphate buffer, and at 0.16 M the final recovery of the control RNA was 96% of the input. After annealing to C_{ot} 100 the 0.12 and 0.16 M pooled fractions containing the single-stranded DNA and the free RNA accounted for 60% of the DNA loaded and for only 5% of the mRNA counts. The 0.5 M phosphate eluate contained the renatured DNA and practically all the RNA counts. The overall yield of the column was close to 100%.

The behaviour of the RNA on the HAP column reproduces perfectly what has been obtained with nitrocellulose filters¹. The retention of the RNA by the column was 95% while the percentage of real RNase-resistant hybrids was only about 20%. We have already shown that this result is not due to artefacts or to extensive base mispairing, as the melting curves of these hybrids are very close to those of native *Xenopus* bulk DNA¹.

The most likely interpretation of this result is that the entire RNA molecule is retained because a small part of it is able to hybridise to repetitive sequences. The 0.5 M eluate was dialysed extensively against H₂O and then 0.1 M Na acetate pH 5. After ethanol precipitation the sample was resuspended in 2 \times SSC and treated with RNase to eliminate the tails of the non-hybridised 'unique' RNA. Twenty per cent of the counts were recovered and incubated with 100 μ g ml⁻¹ of pronase followed by phenol-chloroform extraction to eliminate the proteins. The DNA/RNA hybrid was concentrated, denatured by heating for 15 min at 100° C and diluted several times by addition of ice-cold 6 \times SSC. The denatured DNA was trapped on nitrocellulose filters while the free RNA fragments were recovered in the filtrate. After a short dialysis to eliminate most of the salt, the RNA was ethanol-precipitated and resuspended in different buffers according to the experiment to be performed.

The final sample contained about 50% of the initial RNase-resistant counts and about 5% DNA not retained by the Millipore filters. The purified RNA fragment was then hybridised to DNA in excess. The amount of DNA added to the reaction, together with the radioactive RNA, was about 10% of the total DNA used in each assay and therefore too low to affect the kinetics of the RNA/DNA hybridisation greatly.

The limited amount of radioactive fragments we could recover from a single mRNA preparation raised serious technical problems when we tried to measure the reassociation kinetics of the purified 'repetitive' stretch. The number of increasing C_{ot} values that could be obtained was too low to make significant measurements of the actual rate of reassociation.

Our results clearly indicate, however, that at C_{ot} 100 all the RNA input was RNase-resistant, from which we conclude that the fragments had completely and rapidly reformed hybrids with the complementary repetitive DNA sequences. These results confirm that repetitive, homologous DNA sequences are transcribed into mRNA molecules which carry also the transcript of heterogeneous unique sequences. Moreover, the 'repeated' RNA fragment can be isolated from the ' C_{ot} 100' hybrids, suggesting that the retention of mRNA by Millipore filters and HAP columns is mediated by the formation of a DNA/RNA hybrid between a family of repeated sequences and a complementary RNA fragment.

Size of the repetitive RNA fragment

The size of the isolated fragment has been measured by electrophoresis on 10% acrylamide gels. Fig. 3 shows the pattern obtained using 5S and transfer RNA as external markers; we estimated an approximate length of 50 to 60 nucleotides for the RNA stretch.

A very small amount of heterogeneous heavier material is also observed but the main radioactivity peak seems fairly homogeneous; two conclusions can thus be drawn. First, the matching of the hybrids (also reflected by the melting curves¹) must be good since RNase cannot cut within this region. It is however possible that the original hybrid might be larger than observed here and so the estimated length must be considered a minimal value. Second, the homogeneity of the fragment, as judged by electrophoretic migration, refers only to the size of the repeated RNA sequences in the formed hybrids. Taking into account the heterogeneity of the filter-binding curve¹, we cannot exclude that more than one class of repeated sequences could be transcribed into fragments of final homogeneous length.

Rapidly hybridising fragment at the 5' terminus of the mRNA molecule

To understand the biological meaning of the observed sequence arrangement in mRNA molecules it is relevant to know where the 'repetitive' fragment is located on the molecule. Since it is known that poly(A) is localised at the 3' end of the molecule, it has been possible to show that the repeated fragment is not associated with this end of the RNA.

The isolated 'repetitive' fragment is too short and homogeneous to account for the presence of any poly(A). Also, if the ³H-adenine labelled RNA is incubated with excess DNA to a C_0t 100, RNase-treated and fractionated on HAP most of the poly(A) is found in the flow through of the column, while none is associated with the retained hybrids³.

Since neither of these experiments can exclude the possibility that the RNase A could introduce a specific cut between the protected hybrids and the free poly(A) fragment, we thought it desirable to obtain direct positive evidence about the location of the rapidly hybridising fragment.

A total population of mRNAs was labelled *in vitro* with ³²P using a technique which allows specific labelling of the 5' end of the molecules^{14,15}. As all the mRNA preparations are slightly contaminated by cold tRNA and rRNA, which will also be labelled *in vitro*, a competition system was set up to prevent the hybridisation of these RNA species³. It has been shown that in excess DNA the hybridisation of trace amounts of hot RNA can be efficiently competed with by a five-fold input of cold RNA of the same species^{16,3}. The residual hybridisation obtained under these conditions is about 10%. Our experiments with ³²P-labelled RNA have been run in the presence of fifty-fold excess cold oocyte RNA. Under these conditions the hybridisation of these RNA species to a given amount of DNA (see legend of Fig. 4) should be completely prevented without causing any interference with the reassociation of the mRNA.

Figure 4 shows that when a total population of mRNA is hybridised with excess DNA¹⁷ most of the RNA hybridises to unique sequences. Only about 20% of the RNA rapidly hybridises with repeated sequences. This result confirms that the hybridisation pattern obtained in previous experiments¹ was not due to a qualitatively selected population of mRNA. In fact, the only difference we have been able to detect between total mRNA and RNA extracted with phenol at pH 5 is that the latter seems to be enriched with molecules carrying shorter poly(A) fragments.

If the same batch of mRNA is labelled *in vitro* at the 5' end and the hybridisation in excess DNA is performed (Fig. 4) monitoring the ³²P RNase-resistant counts, a completely different pattern is obtained. All the counts are hybridised at C_0t 100 and the reassociation follows second order kinetics. This should be indicative of a single reassociating species with a $C_0t_{1/2}$ of about 12–25, which in our conditions is slightly faster than rRNA. We therefore conclude that a fragment, transcribed from a family of sequences with a reiteration of about 2,000 copies per diploid genome

is present on polysomal mRNA at the 5' end of the molecule.

Previous results obtained with the filter trapping technique^{1,10}, were indicative of more than one fast renaturing component. In fact about 30% of the RNA was retained by the filters at a very low C_0t (10^{-1}) while the rest of the reaction was following slower kinetics.

The homogeneity of the hybridisation kinetics obtained with the ³²P-labelled RNA may be explained in two ways. The population of RNAs used for the filter trapping experi-

Fig. 4 DNA excess hybridisation of ³H-adenine labelled mRNA and 5' ³²P-labelled mRNA. The ³H-labelled mRNA was prepared from polysomes of 4 h labelled embryos as specified in Fig. 1. The hybridisation was performed in a great excess of DNA¹. A blank value equal to 5% of the input has been subtracted at each point as this was the RNase A resistance of the purified mRNA due to the presence of labelled stretches of poly(A). The same batch of ³H-labelled mRNA was then labelled with ³²P according to the procedure of Ilan and Ilan¹⁴. ³²P-2-cyanoethylphosphate pyridinium salt was prepared according to the method of Pfizner and Moffat¹⁵ (modified to obtain a specific activity five times as great), and was used as a donor molecule. The mRNA was treated with 10 μ g ml⁻¹ of alkaline phosphatase for 1 h at 30° C in 0.1 M Tris pH 8.2, to cleave the 5' end phosphate. To avoid degradation of mRNA, and subsequent formation of artefactual free ends, a nuclease-free preparation of enzyme was used (Boehringer, Mannheim). After phenol and chloroform extraction, the RNA was precipitated in ethanol and resuspended in dimethyl formamide. ³²P-cyanoethylphosphate in dry pyridine was added (15 ml) and the sample evaporated to dryness at room temperature. Dicyclohexylcarbodiimide (2 g) in 15 ml of pyridine was added to resuspend the mixture and the sample was incubated in a stoppered vial for 20 h at room temperature. After drying under vacuum the residue was resuspended in 30 ml water containing 1 mg of *E. coli* tRNA as carrier, centrifuged 30 min at 30,000g and the supernatant was ethanol precipitated. The RNA was resuspended in water adjusted to pH 9 with ammonium hydroxide, and the mixture was heated at 60° C for 75 min to cleave the cyanoethyl group. Before hybridisation, the RNA was further purified on a Sephadex G25 column (1.4 \times 30 cm) to remove the residual free ³²P counts. The peak of radioactivity eluted in the void volume of the column was pooled and ethanol precipitated. The pellet was finally resuspended in 0.12 M phosphate buffer. The resulting RNA sedimented, in sucrose gradients, close to the 4S marker. The yield of ³H counts was equal to about 50% of the input and the yield of ³²P was about five times greater. All the ³H and ³²P counts of this final RNA fraction became completely soluble in TCA after either alkaline hydrolysis or RNase treatment. Alkaline phosphatase treatment removed only the ³²P label. Excess DNA hybridisation was performed under the usual conditions but to obtain reproducible blanks (20–30 counts) every sample was extracted with phenol after the RNase treatment. The samples were then TCA precipitated and counted. The curve is the average of two separate experiments.

FIG. 5 A schematic mRNA molecule.

ments was extremely heterogeneous with a range of sizes varying between 6 and 18S (ref. 1). The reassociation rate of a family of sequences is strictly correlated to their size¹⁹, therefore the heterogeneous pattern of filter trapping we observed might be due to the presence of this wide variation in the size of the reassociating RNA molecules. This size effect is completely excluded using the ³²P-labelled RNA, as during the cleavage of the cyanoethyl group (see legend of Fig. 4) all the RNA is degraded to a size slightly smaller than 4S. The final hybridisation rate obtained with these fragments is slower than that for the original ³H-labelled large molecules and the homogeneity of the curve probably results from the final common length of the fragmented RNA.

Also, although most of the molecules carry a repetitive stretch at the 5' end some of them may have a second, faster hybridising part at a different position in the molecule. When the curve is monitored by the retention of hybrids on nitrocellulose filters², this second repetitive stretch could also hybridise to its DNA complements leading to the trapping of the entire RNA molecule, giving a final heterogeneous pattern of retention. This feature cannot be observed when the hybridisation is monitored by following the RNase-resistant ³²P counts, as in this case only the fragment at the 5' terminus is labelled.

The specificity of the cyanoethylphosphate *in vitro* labelling technique must be considered. In agreement with Ilan and Ilan⁴, after alkaline hydrolysis and DEAE-Sephadex chromatography we recovered, as expected, most of the ³²P counts as pXp. The presence of a small amount of monophosphates (and therefore of 3' labelling) cannot be completely excluded on the basis of this experiment since it is very difficult to purify the RNA from all the free ³²P counts which elute from the DEAE-Sephadex column in the monophosphate region. Significant labelling of the 3' end carrying the poly(A) fragment, however, does not occur, since 90% of the ³²P counts are digested by RNase under conditions which leave the poly(A) stretches intact.

The alkaline phosphatase stage in the procedure might cause some breakage of the mRNA before the *in vitro* labelling. This produces artefactual 5' ends where a phosphate could be introduced during the *in vitro* labelling procedure. The hybridisation pattern expected here, however, would be similar to the one obtained with *in vivo* ³H-labelled mRNA. It can be calculated that with only two randomly introduced breaks per molecule, approximately 70% of the *in vitro* labelled RNA would be expected to behave as 'unique'. This is certainly not the case (Fig. 4) and therefore our results clearly show that significant breakage cannot have occurred during the alkaline phosphatase treatment unless specific cuts were introduced only in the regions containing the 'repetitive' fragment. We have no way to check this possibility at present, because of the size heterogeneity of our mRNA population.

Sequence arrangement on mRNA

Figure 5 shows a diagram of an mRNA molecule based on our experimental results. Every molecule of a heterogeneous population of mRNAs is made up of three main parts. At the 5' end there is a homologous fragment, 50 to 60 nucleotides in length, transcribed from repetitive sequences. This fragment is present on every molecule and is covalently linked to a longer heterogeneous sequence transcribed from the unique part of the DNA. In agreement with reported data

for different kinds of cultured cells^{11,10} we also found evidence that poly(A) is probably added post-transcriptionally at the 3' end of the molecules. Ilan and Ilan¹⁴ reported the existence of a short homologous fragment at the 5' end of insect mRNAs; this suggests that the sequence arrangement we have observed might be a common feature of eukaryotes.

In this respect, it is relevant that experiments done directly on DNA have shown the existence of a pattern of sequence distribution which could give rise to the transcriptional products we observed. Davidson *et al.*²⁰ reported that at least 50% of the genome of *Xenopus laevis* is organised with short (300 nucleotides average) repetitive sequences intermingled with longer (1,000 nucleotides average) unique sequences. The rest of the genome also seems to be organised similarly, but with longer unique sequences interposed. As in this system, few of the intermediate steps of the mRNA maturation in the nucleus are known, it is impossible to make any strict correlation between the sequence sizes observed on the RNA molecules and the described structure of the genome.

The biological roles of the different RNA sequences carried by each molecule are so far unknown, except for the 'unique' part, which supposedly carries the information for protein synthesis. It seems important, however, that the repetitive fragment on cytoplasmic mRNA be in a specific position (5' terminus). It is possible that this sequence plays a role at the level of mRNA maturation in the nucleus and is possibly the result of the partial cleavage of one of the 'hair-pins' known to exist in HnRNA (ref. 21). A more attractive suggestion is that the homologous sequences on different messengers could be involved in translational control mechanisms.

We thank M. B. Benedict for technical assistance and Drs Joseph and Judith Ilan for making their technique available to us before publication. Radio source identified with a neutral stellar object near an unusual galaxy

RECENT improvements in the accuracy of location of radio source positions to 1 arc s have made possible the reliable identification of a number of radio sources with stellar objects of neutral colour (NSO)¹⁻⁴. Two of these have the highest known redshifts, 3.4 (ref. 5), and 3.53 (ref. 6). Others have featureless optical spectra and are probably BL Lac objects⁷ (Carswell *et al.*⁸ and P. A. Strittmatter, private communication). We report here the identification of an NSO of 19 mag close to an unusual blue galaxy, using an accurate radio position obtained at 408 MHz with the Mills Cross of the Molongo Observatory.

The radio source 1107+036 was reported by Munro⁹ and has been identified with a nearby blue galaxy of 17 mag¹⁰ (for reasons explained below) rather than with the NSO of 19 mag noted to the west and closer to the radio position. Figure 1 is an enlargement of a section of prints from the National Geographic-Mount Palomar Sky Survey, which clearly shows both objects. The radio positions in ref. 10 were accurate to ~ 5 arc s and the total number of NSOs within the radio error regions was consistent with chance expectation. Radio and optical positions accurate to ~ 1 arc s are necessary to identify an NSO reliably. A position of this accuracy has now been obtained at Molongo for 1107+036. The improvement principally arises from repeated observations during special calibration sessions, in which a large number of sources with known optical positions are observed on successive days, and other objects of interest are interspersed with these. The main purpose of these sessions is to discover and monitor time-varying sources¹¹ and to test the performance of the aerial.

The radio source 1107+036 was observed on six different days spanning three different calibration sessions. The use of numerous calibrators close to the source and the repeated observation of the source enables the rejection on statistical grounds of occasional results affected by severe ionospheric or meteorological conditions. The result is presented in Table 1 together with the optical position obtained from the sky survey prints. A new optical measurement for the NSO is consistent with that already reported¹⁰ and the mean of the two measurements is given in Table 1.

The identification is highly likely because the probability of a chance association at a separation of 2.1 arc s is about 0.004, based on star counts¹⁰ in the appropriate range of galactic latitude.

The source does, however, differ in one important respect from most NSOs identified with radio sources, in that it has a steep radio spectrum with spectral index 0.99 ± 0.07 . This is a revision of the value quoted by Murdoch and Hoskins¹² and uses the present flux density at 408 MHz of 1.77 ± 0.05 Jy (1 Jy = 1 f.u.). Extrapolation to 178 MHz would indicate at flux density of 4 Jy but the source does not appear in the 4C catalogue¹³. This could indicate self absorption of low frequency but is probably a result of the nearby occurrence of 1108+034 (4C03.21) and 1107+045 (4C04.35). Most radio sources identified with NSOs have 'abnormal' radio spectra¹⁻⁵, (where the term normal implies a reasonably

straight radio spectrum with spectral index steeper than -0.5). It is not clear, however, to what extent the predominance of abnormal spectra may be a selection effect which arises because most of the accurate positions necessary for the identification of NSOs have been obtained at high frequency.

The nearby blue galaxy is an interesting object in its own right. There is an extensive blue envelope of diameter ~ 20 arc s which is apparently non-uniform. The most prominent features are a blue condensation to the north and, on the red print, a curved feature extending outwards from the central region toward the south-east. A high resolution photograph is necessary to test the reality of these features.

The original identification was made with the galaxy¹⁰ despite its displacement outside the error region, because it was found that the total number of galaxies beyond the radio error regions, but within 20 arc s of the respective radio positions, was significantly in excess of chance expectation. Among the various cases in this category, 1107+036 seemed to be one of the more likely cases of a genuine displaced identification. Now that an alternate identification has been found, the question arises as to whether the nearby presence of the galaxy should be regarded as coincidental, or whether the two objects might be associated.

We might question whether all of the galaxy identifications suggested by Hoskins *et al.*¹⁰ with radio-optical separations greater than the error limits might be coincidental. This probability was assessed by them to be 0.007. We note incidentally that Véron and Véron¹⁴ have suggested that radio-optical separations are very rare. There is, however, further supporting evidence for such radio-optical separations for galaxies when measurements are made with the 2.9-arc min beam of the Mills Cross. Separations up to ~ 30 kpc were common for galaxies in Abell clusters¹⁵. Separations of ~ 40 kpc from the radio centroid have been found for galaxies with low-brightness extended components¹⁶. We do not, therefore, believe that all the suggested identifications involving a radio-optical separation should be rejected.

There are two sources apparently similar to 1107+036 that warrant brief mention. The variable radio source 0048-097 has recently been identified⁴ with an NSO, in place of the original identification with a nearby blue galaxy¹⁷, and is

Fig. 1 Red and blue images of the NSO 1107+036 and the nearby galaxy, enlarged from the National Geographic-Palomar Survey prints. The scale marked on the red print is 20 arc s long.

TABLE 1 Molonglo positions for NSO1107 + 036

Radio 408 MHz	11 h 07 min 49.38 \pm 0.07 s	03°37' 52.8 \pm 1.5"
Optical NSO	11 h 07 min 49.25 \pm 0.03 s	03°37' 53.6 \pm 0.4"
Galaxy	11 h 07 min 50.51 \pm 0.04 s	03°37' 56.3 \pm 0.6"

probably a BL Lac object⁷. In this case the NSO is brighter than the galaxy. The second case is 0837+242 (4C24.18) which was identified with a nearby irregular blue galaxy (17. mag, ref. 18) rather than with a stellar object closer to the radio source. Burbidge¹⁹ found a continuous optical spectrum for the stellar object which has been described as blue^{14,18} and as neutral¹⁹. Véron and Véron¹⁴ consider the stellar object to be the identification but J. M. Sutton (private communication) has obtained a more accurate radio position which is 13 arc s from the stellar object. The identification is therefore seriously in doubt.

The one additional case of an NSO within 20 arc s of a blue galaxy is not a convincing argument for associating the blue galaxy with the radio source in either case (0048-097 or 1107+036). In the absence of direct evidence, we consider that further cases need to be found before the association can be justified statistically.

The general nature of neutral stellar objects is not clear, but it is suspected that they are linked to the BL Lac objects (Carswell *et al.*⁸, and P. A. Strittmatter, private communication). Racine²⁰ has suggested that BL Lac (and hence presumably other objects in this class) may represent a particular type of galaxy closely related to N galaxies and Seyfert galaxies. Among other bright BL Lac objects and possible BL Lac objects 1727+50 (ref. 7) was listed as a very compact galaxy²¹, 1101+38 (ref. 22) was listed as an extremely compact galaxy²¹, and AP Lib (1514-24) was classified as an N galaxy²³.

In fact, a problem in classifying the optical counterparts of radio sources is that any morphological classification depends directly on apparent magnitude (and therefore, presumably, distance). It may well be that the NSOs currently being identified are fainter members of the same class of compact objects. The occasional nearby presence of other galaxies would then no longer be surprising because of the known tendency of galaxies to cluster.

We thank P. A. Strittmatter and J. M. Sutton for communicating information in advance of publication. The new optical position was measured by Miss Sue Howard. Search for high frequency optical variations in Vela XR-1

THE binary system associated with the 6.87-mag B0.5Ib star, HD 77581, which is identified^{1,2} with the Vela X-ray source, 2U0900-40, is a good candidate for optical studies with high time resolution because of its relative brightness. A 28-min data set consisting of consecutive integrations of 1 ms was taken on the night of February 25-26, 1973 with the Cerro Tololo 152-cm telescope using an S-20 photomultiplier with no filter. Analyses using power-spectral and cepstrum techniques³ show no significant activity at a level greater than 0.25% in the range from 0.06 Hz to 500 Hz (except for instrumental artefacts at 60, 180, 300 and 500 Hz). No aperiodic variations were detected to a weaker limit (1%-2%); at low frequencies (<10 Hz) increased variance ascribable to atmospheric scintillation was present. This result was confirmed by a separate analysis of about 15 min of data from an observation of 1 h on the night of January 13-14, 1973. That the X-ray emission is actually associated with a degenerate, collapsed (and perhaps invisible) companion to the brilliant supergiant, however, makes a stronger limit very desirable.

Alaska to New Zealand whistler-mode transmission at 6.8 kHz

OBSERVATIONS of whistler-mode signals from v.l.f. communications transmitters have been used^{1,2} to study the magnetosphere in a way similar to the use of naturally occurring whistlers from lightning. Existing naval communications transmitters provide high radiated power (up to 1 MW) but are restricted to transmission at allocated frequencies mostly above about 15 kHz, are not well located geographically for this work and are not often available to transmit special programmes.

We report here one result of an experiment for which we set up a transportable v.l.f. transmitter in Alaska and a receiving station in New Zealand located so as to be approximately geomagnetically conjugate. Since the Otago group already had v.l.f. receiving facilities at Dunedin, New Zealand, the transmitter was set up (by the Aerospace group) at Port Heiden, Alaska, about 200 km from Dunedin's conjugate. The transmitter antenna was a vertical monopole lifted to 1,000 to 1,500 m by balloon. The transmitter and all associated equipment (including power generator) are mounted on trailers so that the installation can be set up or removed in a matter of days. Although transmitter location and frequency are quite flexible, radiated power obtainable is quite low. This varies from a few kW at 21 kHz to about 100 W at 7 kHz. During the event described here the radiated power was only 13 W.

The event occurred about 1 h after local midnight on (Greenwich date) August 27, 1972. The transmitter operated at 6.8 kHz (at 13 W) from approximately 1307 to 1342 GMT. Whistler-mode signals were first detected at Dunedin at about 1324 GMT. Signal strength increased with some variation to a maximum of $35 \mu\text{V m}^{-1}$, before fading again to below detectability at about 1330 GMT.

During this period of good reception, the transmitter was keyed on for 0.5 s in each second from 1326 to 1327:41 and then continuously ("c.w.") to 1329:10 GMT. Before 1326 and after 1329:10 the transmitter sent pulses of varying length and separation. From these the one-hop delay was measured as 1.13 ± 0.01 s. Maximum signal strength ($35 \mu\text{V m}^{-1}$) occurred between about 1328:20 to 1328:40 during c.w. transmission. A short section is shown in Fig. 1.

Twelve whistlers were received at Dunedin during the period 1325 to 1330. Most reached up to 8 kHz and were strongest between 5 and 6 kHz. Eight of these whistlers were 'short' or one-hop and the other four were 'long' or two-hop. None showed echoes beyond 2-hop, or any associated hiss or triggered emission, or any other evidence that duct amplification might be higher than typical.

Fig. 1 Dynamic spectrogram of a short section near 1328:30 UT, using a Rayspan scanning at 48 sweeps s^{-1} . Trace separation corresponds to about $40 \mu\text{V m}^{-1}$. Signal at 6.8 kHz is indicated by arrow.

Although no whistler reached the nose frequency, dispersion analysis using the "linear-Q" technique³ showed that all whistlers travelled in the one duct at $L = 2.92 \pm 0.04$ (invariant latitude 54.2°) with one-hop delay at 6.8 kHz of 1.13 ± 0.01 s. From this it can be safely assumed that the signals from our transmitter travelled in this duct also.

An estimate of the duct amplification can be made by comparing the observed signal strength with that calculated for no duct amplification. Helliwell provides analytic expressions and graphs for making such calculations on pages 64 to 81 of ref. 4. Briefly his method involves calculating the field of the wave transmitted into the duct, the effective cross section, trapping and transmission efficiency of the duct, the field at the duct output (Dunedin end), the absorption through the D, E and F region, and finally the waveguide loss from the duct exit region to the receiver (Dunedin). Although we know the duct latitude by dispersion analysis, we do not know duct longitude and hence the distances Port Heiden—duct entrance and duct exit—Dunedin. If the duct were fortuitously located to minimise these distances (100 km and 160 km respectively) the signal expected would be about $1.5 \mu\text{V m}^{-1}$ to within about 3 dB. The observed signal strength of $35 \mu\text{V m}^{-1}$ thus implies amplification of about 27 ± 3 dB for optimum duct longitude. Higher amplification would be needed for other duct longitudes. Thus if the duct exit had been a "reasonable" 1,000 km from Dunedin, an additional 20 dB of amplification would be required.

Since the observed whistlers were typical and unremarkable, we conclude that duct amplification at night is typically of the order of 30 dB per hop. As a consequence whistler mode signals can be obtained from quite low power transmissions at 'low' (~ 7 kHz) frequencies.

Effect of atmosphere and ionosphere on magnetospheric micropulsation signals

THE large-scale structure of low frequency hydromagnetic waves in the magnetospheric plasma can be understood from observations of micropulsations at the Earth's surface. Signals have to penetrate the ionosphere and atmosphere and although the scale heights of these layers are much less than the scale lengths expected for the magnetospheric phenomena, the behaviour is not as simple as might be expected^{1,2}.

Recent computations³ (also, W. J. Hughes, to be published) allow an analytical approach to the problem.

Dungey¹ split the disturbance seen on the ground into two parts, one part with zero vertical current at the ground and the other with a vertical current. The latter part behaves differently from the former and is in fact strongly screened by the ionosphere. The vertical current at the ground is non-zero and this part of the disturbance therefore has a vertical electric field associated with it, given by

$$\frac{1}{c} (4\pi\sigma + i\omega) E_z = (\text{curl } \mathbf{b})_z$$

where \mathbf{b} is magnetic disturbance and σ is the atmospheric conductivity. Therefore, near the ground

$$E_z \sim \frac{cb_g}{(4\pi\sigma_g + i\omega)l} \quad (1)$$

where l is the horizontal scale length of the disturbance. This vertical electric field is related to the horizontal electric field by Faraday's law so that, also near the ground,

$$\frac{\partial E_y}{\partial z} - \frac{\partial E_z}{\partial y} = \frac{i\omega}{c} b_g \quad (2)$$

where y is the direction of horizontal variation of the micropulsation magnetic field. Using equation (1) in equation (2), together with the approximation

$$\frac{\partial E_z}{\partial y} \sim \frac{E_z}{l}$$

it is clear that if

$$\frac{(4\pi\sigma + i\omega)\omega l^2}{c^2} \ll 1 \quad (3)$$

then

$$\frac{\partial E_z}{\partial y} \sim \frac{\partial E_y}{\partial z} \quad (4)$$

and the disturbance is effectively electrostatic in the atmosphere. Equation (3) is satisfied for $\omega \sim 0.1$ – 0.01 s⁻¹ by any non-uniform disturbance on the Earth.

It follows that because the electric current is divergence free and the conductivity rises markedly with height, E_z decreases rapidly with height. Equation (4) shows that the change of E_y with height is proportional to E_z and, as the numerical integrations show, with any reasonable atmospheric model the horizontal electric field is more or less constant from a height above 20–30 km and will be of the order $h E_{zg}/l$, where h is the scale height for conductivity (and thus for E_z).

This electric field drives both Pedersen and Hall currents in the ionosphere and the increase in magnetic field resulting from the currents, in both the x and y directions, is given by Ampere's Law and is of the order

$$\begin{aligned} \Delta b &\sim \frac{4\pi}{c} \Sigma E_y \\ &\sim \frac{4\pi}{c} \Sigma \frac{h E_{zg}}{l} \\ &\sim \frac{4\pi}{c} \Sigma \frac{h}{l} \frac{cb_g}{(4\pi\sigma_g + i\omega)l} \end{aligned}$$

where Σ is a height integrated ionosphere conductivity. For $\Sigma \sim 10^{13}$ electrostatic units (e.s.u.) $h \sim 10^6$ cm, $l \sim 10^8$ cm and $\omega \sim 10^{-1}$ s⁻¹ the field at the ionosphere is $\sim 10^5$ greater than that at the ground. This part of the disturbance is thus effectively screened from the ground by the ionosphere.

The other part of the disturbance, that is, the part with $(\text{curl } \mathbf{b})_z = 0$ at the ground, behaves more simply. Everywhere at the ground $E_z = 0$ and so the horizontal electric field and magnetic field are related by

$$\frac{\partial E_z}{\partial z} = \frac{i\omega b_{yg}}{c}$$

or

$$E_z \sim \frac{i\omega}{c} z b_{yg}$$

Computations show that this approximation is valid up to the top of the ionosphere. The change in magnetic field produced by the ionospheric current is of the order

$$\Delta b \sim 4\pi b_g \frac{\Sigma d\omega}{c^2}$$

where d is the mean height of the high Pedersen or Hall conductivity region in the ionosphere. For $\omega \sim 10^{-1}$ and $d \sim 10^7$ cm, Δb is of the order of the magnetic field at the ground. At lower frequencies ($\omega \lesssim 10^{-2}$) the ionospheric contribution to this part may be ignored, and the magnetic fields above and below the ionosphere are the same.

As the ionosphere screens only that part with $(\text{curl } \mathbf{b})_z \neq 0$, then $(\text{curl } \mathbf{b})_z$ must be effectively zero for any disturbance seen on the ground, whatever the disturbance in the magnetosphere. The magnetospheric disturbance is determined by the hydromagnetic wave equations and boundary conditions very far from the Earth. A magnetospheric disturbance will generally contain parts of each disturbance described, and thus will not be totally screened.

In a cold plasma (which is a good approximation for most of the magnetosphere away from the equatorial region) there are two wave modes; the isotropic fast mode and the transverse mode which is guided by the magnetic field. The scale length of variation for the isotropic mode is $2\pi A/\omega$ where A is the Alfvén speed. For $\omega \sim 10^{-1}$ – 10^{-2} s⁻¹, and an Alfvén speed of the order of 10^8 cm s⁻¹, the scale length of the fast mode is much greater than terrestrial dimensions. This implies that if the disturbance is localised on the Earth, the fast mode contribution is evanescent and the vertical scale of variation of the disturbance in the magnetosphere is comparable to its horizontal scale on the ground. If boundary conditions are then applied between the ionosphere and the magnetosphere for horizontal scales of about 300 km or greater, the disturbance on the ground is proportional to the transverse mode amplitude in the magnetosphere.

Observations of the localisation in latitude of an event at a given micropulsation frequency^{4,5} suggest that the field line resonances of the transverse hydromagnetic mode are an important source of micropulsations.

At mid and high latitudes, however, where the dip angle is large, the transverse mode has $\nabla \cdot \mathbf{b}_{\text{HOR}} \approx 0$ in the magnetosphere. But on the ground the ionospheric screening ensures that only the part with $(\text{curl } \mathbf{b}_g)_z \approx 0$ will be seen. If the horizontal scale is great enough for the magnetospheric and ground magnetic fields to be directly proportional, then the ionospheric currents must act so as to rotate the horizontal vector of the magnetic field through 90°. In such a case the horizontal polarisation pattern seen on the ground needs to be rotated through a right angle to obtain the magnetospheric pattern.

Features of a disturbance which exhibits a peak at a fixed latitude and a periodic variation in longitude, can be simply outlined. At the latitudinal peak the disturbance should be linearly east-west polarised on the ground. Elsewhere the ground polarisation will be elliptical with the major axis north-south for events which are strongly lo-

calised latitudinally. This result is in agreement with some earlier experimental observations⁵⁻⁸.

In conclusion, the properties of micropulsation signals discussed here seem to be an important feature of at least one class of pulsations; and our studies suggest that to a first approximation the polarisation ellipse on the ground should be rotated through a right angle to obtain the magnetospheric polarisation.

Middle Cretaceous sediments from the eastern part of Walvis Ridge

THE Walvis Ridge is one of the most conspicuous features of the South Atlantic. It extends from near Tristan da Cunha on the Mid-Atlantic Ridge to the African continental margin and has three main segments. The western segment is oriented SW-NE, the central one N-S and the eastern one SSW-NNE. The Walvis Ridge may have kept pace with the opening of the South Atlantic which started in the Early Cretaceous¹⁻⁸, either by transform fault mechanisms^{7,8} or by a mantle hot spot and plume⁹⁻¹². The eastern segment

Fig. 1 Bathymetric map of the eastern segment of the Walvis Ridge showing the location of the seismic reflection profile shown in Fig. 2, and the locations of the sediment samples. a, Site of dredge. Depths in corrected metres. Contours at intervals of 200 m.

Fig. 2 Seismic reflection profile across the northern scarp of the eastern segment of Walvis Ridge and location of the dredged rocks. a, Site of dredge.

is thought to have been built throughout the Middle Cretaceous, that is, between 120 m.y. ago and 80 m.y. ago¹³⁻¹⁵. We report information obtained from an investigation of the age and depositional conditions of sedimentary rock recovered during the Walda cruise of the RV Jean Charcot (April-August 1971).

White chalk fragments containing numerous fossils were recovered from a depth of 2,700 m by a dredge (CH 18 DR 04) on the northern flank of the Walvis Ridge in the centre of the eastern segment (19° 33'S; 09° 01'E) (Fig. 1). Smear slides of the calcareous matrix show mainly coccoliths and micritic calcite. Glauconite and biotite are also present. The most abundant macrofossils are gastropods, remains of echinoderms (regular and irregular urchins: *Holasteroidea*, *Spatangoida*) and bivalves (including *Ostreidae*, *Arcacea*, *Heterodonta* and *Neithea*). One specimen of *Neithea* could be *Neithea cf. shawi* Pervinquière (= *N. coquandi* Péron). The distribution of *N. shawi* is Albian-Cenomanian in the Angola Basin but mostly Cenomanian in northern Africa¹⁶. This specimen is, however, poorly preserved and could belong to the species *N. regularis* Schlotheim. In Europe the distribution of *N. regularis* Schlotheim ranges from Turonian to Senonian (Freinex, personal communication). Thus the macrofossils indicate an Albian-Senonian age. The nannofossils consist mainly of *Lithastrinus floralis* Stradner, *Cricolithus multiradiatus* Kamptner, *C. pemmatoideus* Deflandre, *Loxolithus armilla* (Black) and *Parhabdololithus embergeri* (Noël). These are typical Albian-Cenomanian species. The sediment is therefore tentatively dated Middle Cretaceous, that is, about 100 m.y.BP. This agrees with ages proposed by other authors¹³⁻¹⁵.

Macrofossils are not common in a coccolith ooze. Hypotheses for a depositional environment of the sediments, which might explain the observed association include (1) the coccoliths accumulated in deep water and the macrofossils are thanatocoenoses transported from shallow depths by turbidity currents or some other process; (2) both the coccoliths and macrofossils were deposited in shallow water. We favour the second hypothesis, tentatively rejecting a mixed origin for the sediments because of the distance from the African coast and the absence of local seamounts. A shallow water environment would comply with the ecological needs of the macrofossils. *Neithea*, for example, is commonly found in shallow water Albo-Cenomanian deposits in the Angola Basin¹⁶. Furthermore, coccoliths are epipelagic organisms and cannot be used as precise depth indicators¹⁷. Although they are typical of open sea sedimentation, their occurrence does not necessarily imply deep water.

Geological map of the Horn of Africa and surrounding regions, showing tectonic features and geological formations. The map includes labels for countries like Sudan, Ethiopia, Kenya, Somalia, Djibouti, and Arabia, as well as major bodies of water like the Red Sea, Gulf of Aden, and Indian Ocean. Key geological features include the Afar Depression, Lake Tana, Lake Victoria, and the Belet Wen Fault Zone. A legend in the top right corner details the geological formations and tectonic features, including Mesozoic, Eocene, and Miocene sediments, and recent faulting. A scale bar at the bottom left indicates distances up to 300 km.

Legend:

- Formations unaffected by important Mesozoic - Recent faulting:
 - Pliocene - Recent sediments
 - Eocene - Miocene sediments
 - Eocene - Miocene volcanics (Trap series)
 - Mesozoic sediments and Precambrian
- Regions affected by Mesozoic - Recent faulting:
 - Miocene - Recent rifting
 - Jijiga - Belet Wen Fault Zone
 - Mekele Faulting
 - Pliocene - Recent faulting in Afar parallel to older trends
 - Mekele trend in central Afar
 - Jijiga - Belet Wen trend

FIG. 1 The geology and large scale structure of the area around the Afar Depression.

The faults affect at least the lower part of the Trap Series basalts, which are considered to be mainly of Oligocene-Miocene age in southern Ethiopia⁶. The intercalation of the lowermost basalt flows with Cretaceous(?) sandstones near Jijiga⁶ does, however, raise difficulties in the assignation of a precise lower age limit for the faulting. A further consideration here is that the main period of faulting could have preceded the basalts. An upper age limit for the faulting is obtained from the observation that they are cut by the

ENE-trending faults of the southern margin of the Afar Depression, which are of Lower–Mid Pliocene age⁷.

Tectonic conditions in the Afro–Arabian region have changed considerably with time. In the case of the Mekele–Northern Somalia movements there is a long time gap before later tectonic activity and we follow Sowerbutts⁸ by suggesting that this is a graben structure related to a Cretaceous Gondwana plate separation (India–Africa?), and that it is not merely an early phase of the present Afro–Arabian movements.

The tectonic relationships of the Jijiga–Belet Wen faulting are more problematical. Movement was possibly dextral, accommodating early plate separation across the Gulf of Aden, unaccompanied by Red Sea movements. This view is in direct contrast to that of Burek⁹ who suggested that such early opening of the Gulf of Aden was accommodated by sinistral transcurrent movement along the present Red Sea, and considered the Harar–Somali plateau to be a single rigid unit. The Gulf of Suez is a key area here. If the transcurrent faulting postulated by Youssef¹⁰ and others is substantiated, our work now suggests a third and more exciting possibility: an independent lower–Mid Tertiary transcurrent movement along the entire Suez–Red Sea–Jijiga–Belet Wen line which determined the locus of later plate separation. In Afar the ‘oceanic’ Erta’Ale volcanic range¹¹ is perfectly aligned on the Jijiga–Belet Wen structure.

It is also clear that planes of weakness along these structures, and the Mekele faulting, have locally controlled the detailed trend of later faulting within Afar. NNW–SSE (Red Sea trend) faulting occurred in the Aisha area north and north–northwest of Jijiga both before and after extrusion of the post-rifting Pliocene flood basalts¹² although this trend of faulting is uncommon elsewhere in southern Afar. Similarly WNW ‘Mekele trend’ faulting is seen in both pre-Tertiary rocks and in Pliocene flood basalt terrains in the southern Danakil Alps and in the Assab–Tendaho region¹³, where diamond-shaped interference patterns occur between WNW and NNW (Red Sea trend) faulting. The reappearance of these fault trends cutting Pliocene flood basalts lends further support to the view that substantial regions of the Afar are underlain by attenuated continental crust.

Tin mineralisation above mantle hot spots

MANY important tin belts of Phanerozoic age, including those in Bolivia, Mexico, Alaska, Malaysia–Indonesia, eastern Australia and western Europe, are believed to have formed above subduction zones at convergent plate margins^{1,2}. If the late Tertiary mineralisation in the southern part of the Eastern Cordillera of Bolivia is representative of this type, then the mineralisation occurred above the deepest parts of subduction zones with the tin perhaps related to partial fusion of subducted oceanic lithosphere³.

In addition to tin deposits at active or inactive convergent plate margins, and Precambrian tin-bearing pegmatites (for example, Congo and Western Australia), there is a third genetic type of economically important tin deposit, which is discussed here. This type formed away from lithospheric plate boundaries, in intraplate environments, and is represented by major deposits on the Jos Plateau in Nigeria^{3,4} and in Rondônia and adjoining states of southern Amazonia, Brazil^{5,6}. Smaller deposits occur in the Air and Zinder areas of Niger⁷, at Mayo Darlé in Cameroun⁸, in the Hoggar massif of southern Algeria⁹ and its extension into the Adrar des Iforas in Mali, at Sabaloka in northern Sudan¹⁰, in south-eastern Egypt¹¹, in the Tibesti area of Chad, in southern Morocco, and in the Damaraland province of South-west Africa^{11,12} (Fig. 1). Tin deposits in Transbaikalia and Mongolia are also of this type (N. Varlamoff, personal communication, 1973).

All of these deposits are associated with small, alkaline and peralkaline granite plutons of anorogenic character—the Younger Granites of Africa—that cut discordantly through the basement which is commonly of Precambrian age. The important Nigerian^{3,4} and Rondônia^{5,6} examples are typical and occur in circular to oval volcanic–plutonic complexes 5 to 20 km wide. These are characterised by early rhyolitic volcanics that are succeeded by multiple granitic intrusives, the emplacement of which was commonly controlled by ring fracturing and cauldron subsidence. Basic and intermediate rocks are also present at some centres. The granites and their porphyritic equivalents are rich in fluorine, containing accessory fluorite and topaz. Mineralisation is in the form of cassiterite accompanied by topaz, lithia mica and some wolframite in greisens and swarms of quartz veins in the roof zones of biotite granites. The complexes in certain areas, such as Hoggar¹³ and Transbaikalia–Mongolia, lack ring structures and may represent a deeper level of emplacement. Although mineralogically similar, the tin deposits in South-west Africa are somewhat different since many occur in pegmatites; at one locality, however, a stockwork of quartz veins is mined^{11,12}.

The tin-bearing, subvolcanic complexes occur in variously oriented lines, several of which constitute elongated belts, approximately 300 to 400 km long, in Nigeria, Rondônia, South West Africa (Fig. 2) and elsewhere. Progressive age trends along the lines of complexes have been claimed^{14,15} but are not strongly supported by the available radiometric data^{16,17} (Fig. 2).

Radiometric dating has demonstrated emplacement of the stanniferous complexes over a protracted time interval: late Precambrian (around 1,000 m.y. ago) in Rondônia^{18,19}, Cambrian in the Hoggar⁹ and at Sabaloka in Sudan¹⁰, Carboniferous in Air²⁰, Jurassic in Nigeria^{21,15}, Jurassic and Cretaceous in South West Africa²², Cretaceous in Trans-

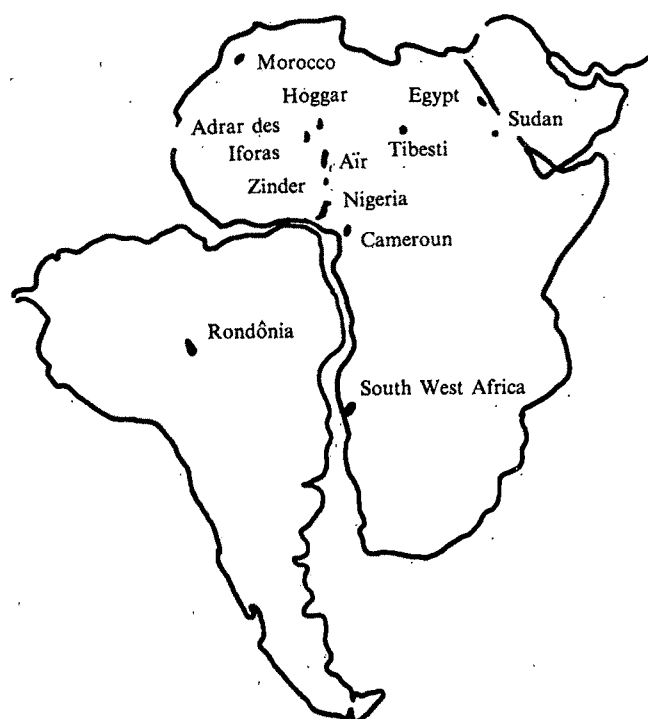

FIG. 1 Areas of tin-bearing, alkaline granitic complexes plotted on a pre-drift reconstruction of Africa and South America. The tin-bearing complex in Cameroun was, however, emplaced after the inception of spreading in the South Atlantic in the early Cretaceous²⁴.

baikalia-Mongolia (N. Varlamoff, personal communication, 1973), and Eocene at Mayo Darlé in Cameroun⁸.

The concept of hot spots or mantle plumes was introduced by Morgan^{23,24} after the earlier ideas of Wilson²⁵. Hot spots are considered to be manifestations of solid-state convection in the lower mantle, and consist of vertical columns or plumes of ascending primitive mantle material. Within the asthenosphere the plumes spread laterally^{23,24}, producing, in some cases, rifting and consequent separation of plates of continental lithosphere²⁶. The fixed mantle plumes are considered to 'burn' through lithospheric plates, thus giving rise to localised igneous activity. At the outset, when the lithosphere is continental, this activity is represented by alkaline magmatism including alkaline granitic, subvolcanic complexes^{14,15,26}, whereas once oceanic crust has been generated the plumes give rise to basaltic oceanic island chains or to aseismic ridges^{23,24,25}.

I therefore propose that the tin-bearing, alkaline granitic complexes in Nigeria, Rondônia and elsewhere were generated above mantle hot spots during a number of brief intervals since the late Precambrian. In all cases the effect of the hot spots seems to have been limited to domal uplift and the emplacement of linear belts of complexes, and activity apparently ceased before the inception of the rifting stage proposed by Burke and Dewey²⁶. In many cases the plumes sought out fundamental breaks in the continental lithosphere and these now seem to control the location and linear array of the stanniferous complexes^{16,17,20,27}. The extents of the tin-bearing belts (Fig. 2) are presumed to reflect the dimensions of the hot spots that produced them and not to indicate widespread migration of magmatism resulting from differential motion between the plumes and the overlying lithosphere^{14,15}.

Economic concentrations of tin are traditionally thought to have been derived from the continental crust (see ref. 28). The concept of tin mineralisation above rising plumes of mantle material suggests, however, that the mantle may be a possible source for the tin and accompanying tungsten and fluorine. A source in the mantle is difficult to prove be-

cause extraction from continental lithosphere, by magmas or magmatic heat provided by rising plume material, cannot be easily discounted. Initial $\text{Sr}^{87}/\text{Sr}^{86}$ ratios of 0.721 and 0.718 determined for samples of granites from complexes in Nigeria²⁹ and Rondônia¹⁸ suggest that significant amounts of the granitic rocks associated with the tin deposits have a crustal source, a hypothesis also supported by other workers²⁶. Much lower initial Sr isotope ratios have, however, been obtained for some granitic units of the White Mountain plume trace in New Hampshire³⁰, possibly indicating a subcrustal origin for their parent magmas. In Nigeria, tin potentially available for extraction, occurs in pegmatites in the Precambrian basement³¹. The abundance of boron, beryllium and tantalum in these deposits and the virtual absence of these elements from the Jurassic tin deposits have been cited as evidence against the hypothesis of remobilisation of Precambrian tin²⁷, unless some mechanism for element segregation is proposed. The rather widespread occurrence of tin in association with anorogenic, alkaline granitic complexes and, perhaps more significantly, its presence along the full length of belts of complexes, also tend to decrease the likelihood of a source in remobilised Precambrian deposits. Furthermore, the absence of significant amounts of the more common base metals from these complexes seems to preclude anatexis or assimilation of unmineralised Precambrian crustal rocks as an origin for the tin. Although some of the granitic rocks are derived at least in part from the continental crust, the evidence, although far from unequivocal, seems to favour a source in the mantle for the tin (compare with ref. 27).

Support for a mantle derivation of lithophile elements at hot spots is provided by evidence from two localities at which continental crust is absent. Blocks dredged from the axial trough of the mid-Atlantic Ridge in the vicinity of the Azores hot spot show evidence of hydrothermal attack and have high contents of several heavy metals, including tin³². At the Iceland hot spot, granitic rocks derived from parent magmas of mantle origin contain concentrations of molybdenum³³, an element which has a geochemical affinity to tin and which occurs with it in some of the complexes (for example, Nigeria⁴ and Sudan¹⁰).

The generation of tin mineralisation above some hot spots and not above others (White Mountain magma series, western Scotland Tertiary province) might reflect either an inhomogeneous distribution of tin (or fluorine) in the mantle or

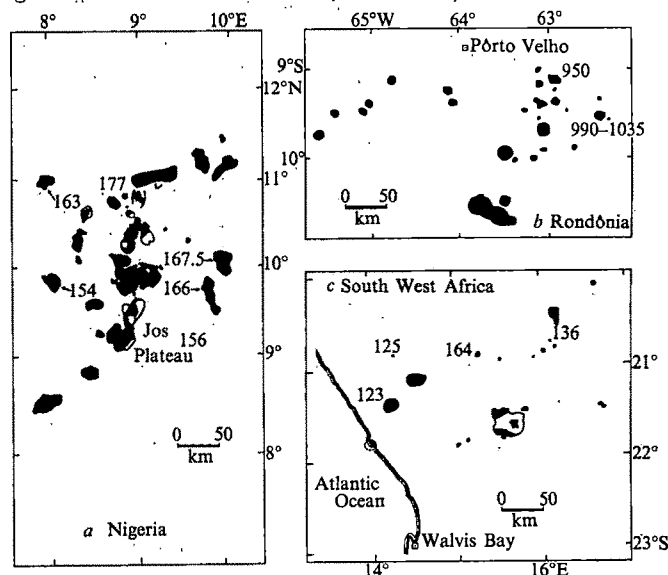

FIG. 2 Linear distribution of tin-bearing, alkaline granitic complexes within elongate belts in a, Nigeria; b, Rondônia; and c, South West Africa. Radiometric ages (numbers) in Nigeria from Jacobson *et al.*²¹ and van Breemen and Bowden¹⁵; in Rondônia from Priem *et al.*¹⁸; and in South West Africa from Siedner and Miller²².

the propagation of mantle plumes, each with a different tin (or fluorine) content, from several levels in the mantle.

The concept of tin mineralisation related to granitic complexes of alkaline type generated in intraplate environments, and unrelated to arc-trench systems, should be useful in the search for ore. In poorly exposed regions, such as Rondônia, the observation that hot-spot activity commonly gives rise to several lines of complexes within an elongated belt (Fig. 2) could facilitate the delimitation of areas for more detailed exploration. Tin deposits might also accompany felsic differentiates at some hot spots in the ocean basins.

Discussions with Drs J. W. Stewart and N. Varlamoff and review of a manuscript by Drs K. Burke, Stewart and Varlamoff are gratefully acknowledged. The paper was prepared during tenure of a Shell Postdoctoral Research Fellowship.

Nature of South Africa's Cape Fold Belt

THE report by Gough¹ of a probable ridge on the highly conductive zone of the upper mantle may be of considerable significance in understanding the deformation of the Palaeozoic trough which became the Cape Fold Belt of South Africa. Until the results of the extended magnetic survey are available, detailed interpretation would be premature, but a few comments may offer guidance for future geophysical work.

The Cape Fold Belt is difficult to explain on plate tectonic models, since (a) it shows a complete lack of any significant igneous or regional metamorphic activity, and (b) it consists of two folded chains almost at right angles, the main one trending E-W, and the smaller one at its western end NNW. These two belts meet at what can best be described as a convergence, since both swing round to a SW direction and merge (Fig. 1).

I have suggested² that an explanation should rather be sought in terms of vertical tectonics and gravity sliding, and a model based on this premise was worked out. The immediately relevant part of this model involved uplift of the southern flank of the main depositional trough (whose axis of maximum subsidence runs just north of the present-day mountain belt) to provide the slope on which gravity sliding took place. It seemed necessary, however, to explain certain zones of more intense folding which occur just north of the major E-W faults, and it was suggested that these faults were active at a very early stage, and with downthrows to the north, forming a series of steps down which gravity sliding took place.

At a later stage, during the breakup of this part of Gondwanaland, the prevailing crustal tension would have induced new movement along these existing lines of weakness but this time with downthrows to the south, as seen today.

The conductive anomaly as shown in Gough's Fig. 1 underlies an area of maximum uplift indicated by the outcropping of late Precambrian basement, on the north side of a major fault line, and it is therefore important to know whether the anomaly is confined to the vicinity of the fault, or whether it extends much further southward (the latter is implied by Gough's statement (ref. 1, page 94) that less than half the anomaly was covered by the array of magnetic stations and by Fig. 9 in ref. 3). It is also important to know whether the same or similar anomalies are associated with other fault lines further south.

Gough suggests that the conductive anomaly may pass eastwards into the gravity anomaly described by Hales and Gough⁴, which is associated with the Cretaceous-filled Algoa basin on the depressed southern side of one of the major

FIG. 1 The Cape Fold Belt.

faults. If, however, there is any close connection between the proposed upward bulge (I prefer this term to 'plume' in this context) on the surface of the highly conductive mantle and the crustal uplift, the conductive anomaly should pass north of the gravity anomaly; it will be interesting to see what the extension of the magnetic survey reveals.

The basic mechanism I invoked for the formation of the Cape Fold Belt was one of vertical movements of fault-defined blocks but no driving force for such movements could be suggested at that time. Clearly, however, if Gough's interpretation of the conductive anomaly is correct, and if such linear mantle bulges can form and decay over long periods, they could provide an adequate explanation for 'keyboard tectonics' in the overlying crust and thus may explain not only the recent uplift of the Cape mountains but also their earlier generative stages.

I thank Dr R. A. Scrutton and C. J. Harnady for discussions.

Oxidation of natural olivines

THE oxidation of olivine is a commonly recognised natural phenomenon and has been investigated experimentally using crystallographic and thermodynamic techniques^{1,2}. It is generally believed that the oxidation of the olivine occurs by initial breakdown of the fayalite component, and subsequent reaction with the forsterite component, to give magnetite and orthopyroxene³. The oxidation of olivine of composition Fo₈₀ can be envisaged as two part reactions:

that is,

In natural olivines such a reaction is commonly represented by partial or complete replacement of the olivine by orthopyroxene-magnetite aggregates. A variation of this reaction is, however, observed in several suites of Precambrian olivine-bearing cumulate rocks which are intrusive into granulite facies gneisses in the western Musgrave Block in central Australia. In such cases a compositional control on the oxidation process is apparent.

(1) In relatively fayalitic olivines (Fo₈₃₋₇₈), olivine is partially or completely altered to granular orthopyroxene-vermicular magnetite aggregates.

(2) In more forsteritic olivines (Fo₇₈₋₈₄), primary spinel inclusions in the olivine are surrounded by thin (0.01 to 0.2 mm) rims of fibrous to granular orthopyroxene. Small quantities of vermicular to granular dark green spinel are commonly intergrown with the orthopyroxene. The spinel core is largest where associated with the thickest rims, suggesting that the primary spinel has grown by the addition

of reaction product spinel. Limited electron microprobe data suggest that both spinel types are of similar picotite composition. Spinel inclusions in other phases are not rimmed.

(3) In the most forsteritic olivines (Fo₈₅₋₈₈), no signs of alteration were observed even though euhedral green spinel inclusions were present.

It is believed that the orthopyroxene-magnetite intergrowths in the more fayalitic olivines result from subsolidus oxidation by the type of reaction shown for olivine of composition Fo₈₀.

Such a reaction involves a volume decrease of approximately 3%. Relative volumes of one magnetite to three enstatite would be produced and this is approximately what is observed. The orthopyroxene produced would be much more Mg-rich than the primary olivine as a result of the oxidation of the fayalite molecule. Both optical and electron microprobe examinations support this prediction.

Granular orthopyroxene and opaques, apparently pseudomorphous after olivine, have been reported in granulite facies rocks apparently penetrated by a transient oxidising fluid phase⁴. Very large areas of the Adirondacks granulite facies terrain have undergone oxygen isotope exchange with some pervasive fluids⁵. The cause of oxidation in the central Australian rocks is, however, unknown. The oxidation may be related to the development of interstitial hydrous fluids, because olivines of composition Fo₈₅ in the Kalka Intrusion are only oxidised in rocks containing biotite. Alternatively, reheating during post-consolidation deformation in the area may have increased oxygen fugacity⁶.

The oxidation is relatively late stage. Coronas typical of the subsolidus high pressure olivine-plagioclase reaction (olivine + plagioclase → orthopyroxene + clinopyroxene + spinel) are commonly observed in this area. In some cases these double coronas surround orthopyroxene-opaque aggregates, indicating that oxidation occurred after the olivine-plagioclase reaction.

The orthopyroxene-spinel intergrowths presumably formed by similar oxidation of more magnesian olivines in the presence of spinel:

The spinel is picotite, (Fe, Mg) (Al, Fe, Cr)₂O₄, which corresponds to the magnetite, FeFe₂O₄, in the more iron-rich oxidation reaction. The presence of chromium in at least some olivine lattices is indicated by the chromite⁷ or chrome magnetite exsolution plates in some of the olivines from the area. The chromium was probably originally incorporated into the olivine as Cr²⁺ in isomorphous substitution with Mg²⁺ and Fe²⁺ (ref. 8). Part of the equivalent oxidation reaction for more magnesian olivines could therefore be:

that is, the spinel phase would contain some chromite component.

The origin of the aluminium in the spinel is more difficult to explain. It may have been derived from the associated primary spinel inclusions (as could the chromium) which were subsequently homogenised with respect to the vermicular spinel. The alternative source, Al-bearing phases (for example plagioclase) outside the olivine, involves diffusion problems because movement would need to be through the olivine lattice. It is, however, interesting to note that Muir and Tilley⁹ propose movement of Mg, Fe and Si through olivine lattices during similar oxidation processes in some Kilauean picrite basalts.

The lack of oxidation in the most forsteritic olivines, even in the presence of primary spinel inclusions, indicates the greater stability of the more magnesian olivines under oxidising conditions.

I thank Dr R. W. Nesbitt for critically reading the manuscript and for supervision. The study was financed by a

Commonwealth Postgraduate Award and an Australian Research Grants Committee grant to Dr Nesbitt.

Stream abrasion of flint implements

Most finds of European Lower Palaeolithic flint artefacts are made from ancient river gravels, either as what are assumed to be concentrations of freshly made implements, suggesting an occupation site, or as abraded material indicating stream redeposition. Verbal description of any abrasion is inaccurate, because lightly abraded specimens may appear fresh to the naked eye. The widths of ridges can be measured on implements with a microscope, thus allowing unworn artefacts and distinct assemblages within a given population to be identified.

When flakes are struck off a flint nodule, either by natural or human agency, the resulting flake scars are separated by a narrow ridge, which is extremely sharp in the fresh state. As the nodule becomes abraded the width of the ridges increases and is easily measurable. The abrasion rate is proportional to the relative hardness of the flint, the velocity of the current, the shape of the nodule or implement, and the particle size distribution of the material present in the transporting medium.

Ridge widths can be measured by placing the artefact under a microscope with incident light from two separate sources converging on the ridge. At least 25 ridges from each

FIG. 1 The fresh ridge. Average width 5 μm . Magnifications of Figs 1-6, $\times 75$.

FIG. 2 The appearance of stress cracks. Average width 15 μm .

side of the implement must be measured. Care should be taken to avoid those that have been affected by human use. A suitably calibrated eyepiece and a magnification of $\times 75$ should permit accuracy of $\pm 0.1 \mu\text{m}$. Various chemical coatings, for example silver nitrate, may be used to improve the optical properties of flint for photography, but these tend to obscure the ridges. Direct comparison of the ridge widths of the components of an assemblage is then possible, and may easily distinguish unworn material.

FIG. 3 A 'braided' ridge. Average width 53 μm .

Figures 1-6 show stages in the natural abrasion of a ridge. They illustrate the process and act as standards for the terminology employed. Figure 1 shows a fresh ridge photographed at a magnification of $\times 75$ in incident light. The ridges have average widths of $5 \mu\text{m}$. The abrasion process consists of both chipping of the implement by other natural and humanly worked nodules during transport, and of a slow grinding down of the ridge by an abrasive consisting of the finer elements in the load carried by the stream. The chipping process is much more active soon after the beginning of the abrasion but continues throughout the process at the places nearest to the centre of gravity of the nodule. Initial stages are marked by the appearance of stress cracks (Fig. 2) which develop a 'braided' appearance (Fig. 3). The braiding is caused by pebbles hitting the ridge at an acute angle and striking off microscopic flakes. The braided ridge is then ground away (Fig. 4), causing a gradual increase of ridge width, irrespective of the flaking angle of the ridge. An alternative sequence involves the rapid appearance of percussion craters, caused

TABLE 1 Correlation between observed ridge widths and commonly used verbal descriptions

Observed ridge width (μm)	0-10	10-20	20-50	50-100	100-200	200-300	300+
Common verbal description	Mint condition	Very fresh	Fresh	Slight abrasion	Abraded	Heavily abraded	Very heavily abraded
Suggested index value	0	1	2	3	4	5	6

FIG. 4 A 'braided' ridge subjected to grinding in fine clay. Average width 34 μm .

by the impact of a heavy pebble (Fig. 5). The final product is, however, always a smooth ridge crossed by hairline cracks (Fig. 6). The worn ridge may attain a width of 4 mm in heavily abraded material. The nature of the abrasion process is largely a function of the type of abrasive and it is possible to distinguish implements that have been abraded in different environments. If the abrasive is fine grained, such as silt or clay, the relative abrasion is very slow but the rounded appearance of the ridge (Fig. 6) is attained very quickly. Experimental verification of these processes may be obtained by abraiding freshly made implements in a tumbling mill, or sandblaster, with different abrasives and concentrations.

Table 1 shows a correlation between the observed ridge widths and the commonly used verbal description of abra-

FIG. 5 Ridge showing some grinding and percussion craters formed by the impact of large pebbles. Average width 81 μm .

sion. An 'abrasion index' value is suggested, based on these metric criteria, facilitating easy quantification of results.

Using these methods it may be possible to define the depositional environment of stray artefact finds by commenting on the textural character of the abrasive material present in the stream, and to distinguish groupings within apparently homogeneous artefact population. In several cases doubt has been cast on supposedly *in situ* assemblages, which now appear to have been stream rolled. I have recently examined a late Lower Palaeolithic assemblage from river gravels at Great Pan Farm (Newport, Isle of Wight). It was at first

FIG. 6 Heavily abraded ridge showing the final rounded appearance, crossed by fine hairlike cracks. Average width 279 μm .

thought that the implements were manufactured at a nearby occupation site, implying that they were virtually contemporary with the gravel deposit, because they appeared totally unabraded. Closer examination showed that many exhibited clear traces of stream abrasion, and variable abrasion index values. It was therefore concluded that the material represented a random accumulation produced by selective stream redeposition, necessitating a re-examination of the typological characteristics of the false 'assemblage'.

A study of the standard typological sequences using these methods may emphasise the need for caution in interpreting implement associations.

I thank Mr A. M. ApSimon and Dr D. P. S. Peacock for help and criticism. The idea of obtaining experimental verification of the abrasion process was developed on the basis of suggestions and practical help from Peacock.

BIOLOGICAL SCIENCES

Virus productive transformation of marsupial cells by Schmidt-Ruppin strain of RSV

Rous sarcoma virus (RSV) transforms different species of mammalian cells. The RSV genome is usually not fully expressed in such cells and the virogenic type of virus-cell interaction is obtained^{1,2}. One exception was, however, noted by Svoboda and Klement³ in the case of some hamster tumours induced by Prague strain of RSV (PR RSV) which were found to produce traces (about 1 ID₅₀ per 2.5 g tumour tissue) of infectious RSV.

In order to establish a suitable RSV-producing system in mammalian cells which would be well defined karyologically, we used the marsupial cell line PtK 1 originally derived from the kidney of rat-kangaroo (*Potorous tridactylis apicalis*) by Walen and Brown⁴.

Cells were cultured in medium 199 supplemented with 20% foetal bovine serum. For the transformation, 1.5×10^6 PtK 1 cells were mixed either with 6.4×10^6 resistance-inducing factor (RIF)-free Brown Leghorn chicken fibroblasts (BLEF) infected with Schmidt-Ruppin strain of RSV (SR RSV), or with the same amount of SR RSV-infected BLEF cells which were irradiated with 7,100 R. The mixed cell cultures were designated RSPtK 1 and RS(X)PtK 1, respectively. SR RSV used (SR RSV K18) represents the pure subgroup D virus isolated from a single focus which appeared in the mixed culture of virogenic mammalian cells and chicken fibroblasts⁵. Mixed cultures as well as control PtK 1 cells were subcultured in Roux bottles and split in a ratio of 1:3 at intervals of 3–10 d.

The clone RSPtK 1/K1 was derived from RSPtK 1 cells after 3 month cultivation by picking a single colony of cells containing refractile cells. For colony isolation, a stainless steel cylinder fixed with a silicone grease to the bottom of the dish was used. The plating efficiency of RSPtK 1 cells was 1%. RSPtK 1/K3 clone was isolated by seeding one cell with a micropipette on the feeder layer of X-irradiated (7,000 R) PtK 1 cells prepared on Petri dishes. The growing clone was obtained in one out of ten dishes.

After 4 month cultivation the cell lines were checked for the presence of avian gs antigen using the immunofluorescence method. This antigen was detected in both RSPtK 1 and RS(X)PtK 1 cells.

Fig. 1 Culture medium (10 ml) from virus producing RSPtK 1 and control PtK 1 cells labelled for 24 h with $10 \mu\text{Ci ml}^{-1}$ of ^3H -uridine or ^3H -thymidine was clarified by centrifugation at 10,000 r.p.m. for 10 min and layered over 50 ml 10%–58% linear sucrose gradient. The samples were centrifuged in the MSE 3 \times 65 ml rotor in a MSE 65 MkII ultracentrifuge at 20,000 r.p.m. at 6° C for 4 h. Fractions of 2 ml were collected from the bottom and assayed for sucrose concentration and after TCA precipitation for radioactivity. The maximum radioactivity of incorporated ^3H -uridine was found in the peak of density 1.156 which is characteristic of C-type RNA viruses. No radioactivity was found after ^3H -thymidine labelling, as well as in the control cells. Δ — Δ — Δ , ^3H -uridine, RSPtK 1; \square — \square — \square , ^3H -uridine, PtK 1; \square — \square — \square , ^3H -thymidine RSPtK 1.

In addition, all cell lines were tested for the presence of RSV genome and infectious RSV. Living cells from RSPtK

TABLE 1 History and biological properties of PtK 1 cells and RSV-transformed cell lines derived from them

Designation of the cell line	Mode of transformation	Morphology	Generation time (h)	Plating efficiency in soft* agar	Modal chromosome No.	Virus production (FFU ml ⁻¹)
PtK 1	—	Normal	45	<10 ⁻⁶	11	0
RS(X)PtK 1	Co-cultivation with chicken fibroblasts infected with SR RSV, irradiated with 7,000 R	Normal to transformed	34.5	<10 ⁻⁶	11	12

* Average number from two dishes

Fig. 2 Morphology of RSPtK 1 cells which shows a non-oriented pattern of growth and presence of stellate and fibroblastoid cells ($\times 55$).

1, RS(X)PtK 1 and RSPtK 1/K1 cells gave rise to Rous sarcomas after injection of relatively small numbers of living cells (about 10^3). Moreover, infectious virus was detected when chickens were injected with cell-free culture fluid collected from full-grown cell layers, either centrifuged at $3,000g$ for 30 min or filtered through Millipore membranes ($0.22 \mu\text{m}$ pore size).

The mean titre of virus as measured by the focus assay method⁶ varied from 1.2×10^4 to 5×10^4 FFU ml^{-1} between different lines with the exception of RSPtK 1/K3 clone kept for a long period of time in tissue culture where RSV production was lower (Table 1).

RSPtK 1 cells were also studied by electron microscopy. Cells were fixed with glutaraldehyde, scraped with a rubber policeman, pelleted, post-fixed with osmium tetroxide and after dehydration the pellets were embedded in Araldite. Ultrathin sections were cut with a Reichert Om U 2 ultramicrotome, contrasted with uranyl acetate and lead citrate and observed with a JEM 7 electron microscope. Early stages of budding of virus particles as well as mature C-type particles were clearly identified.

Fig. 3 Morphology of PtK 1 cells. Epithelioid cells with the tendency to form packed colonies ($\times 55$).

If RSPtK 1 cells were grown in the medium containing ^3H -uridine and the supernatant was centrifuged in 10–58% sucrose density gradients a peak of radioactivity at a density of 1.16 g cm^{-3} was detected (Fig. 1). The virus isolated from RSPtK 1/K1 cultures was neutralised by two log dilutions with the specific anti-SR RSV-D antiserum⁵ to the same extent as SR RSV-D virus. Transformed cell lines cultivated

over a year tended to lose their virus-producing capacity and to become virogenic.

Further biological parameters of all cell lines are summarised in Table 1. RSPtK 1 and RSPtK 1/K1 cell lines plated in soft agar⁷ and were morphologically transformed. Figure 2 illustrates the morphology of RSPtK 1 cells which displayed a non-oriented pattern of growth; the cell population consisted of stellate and fibroblastoid cells. The generation time of RSPtK 1 cells was half that of control PtK 1 cells. In contrast to it, PtK 1 and RS(X)PtK 1 cell lines did not form colonies in soft agar and retained the epithelioid morphology with a tendency to form packed colonies on the solid substrate (Fig. 3). But after prolonged passages RS(X)PtK 1 cells also became morphologically transformed.

Fig. 4 Karyotypes of PtK 1 cells and RSV-producing cell lines derived from them ($\times 544$).

All cell lines had the eleven chromosome stemlines (Fig. 4) and the frequency of chromosomal damage was not increased above the control background in the RSV-producing lines.

The model of RSV-transformed PtK 1 cells offers a unique possibility for investigating RSV production on a permanent cell line which is well defined karyologically and for studying which host cell chromosomes are necessary for the maintenance of the virus-producing state.

This investigation was aided by a grant from the Jane Coffin Childs Memorial Fund for Medical Research (U.S.A.). We thank Dr J. E. Shannon, American Type Culture Collection, Rockville, Maryland for providing the cell line PtK 1.

DNA synthesis in 'nuclear monolayers' from BSC-1 cells infected with herpes virus

HERPES simplex viruses (HSV) produce latent (as well as overt) infection in man. Recent evidence seems to indicate that they can also transform mammalian cells in culture^{1,2}. Furthermore, seroepidemiological³ and molecular hybridisation⁴ studies have suggested a possible causal relationship between genital infection with HSV type II and cervical cancer.

A detailed understanding of viral DNA replication is necessary to elucidate the process of HSV infection. Considerable information has been obtained about the changes, caused by infection, in the soluble enzymes associated with DNA synthesis, for example, the induction of a virus-specific DNA polymerase^{5,6} and deoxynucleoside kinase^{7,8}, soon after infection.

In recent years, however, the use of carefully isolated, insoluble replication complexes (or toluenised cells) has transformed our views on the roles of soluble polymerases in the replication of the bacterial chromosome⁹⁻¹¹. It therefore seemed likely that similar insights into the mechanism of herpes DNA replication might be obtained with an analogous mammalian system. Friedman and Mueller¹² have demonstrated the ATP-dependent incorporation of deoxynucleoside triphosphates into the DNA of isolated HeLa nuclei and showed that this activity was correlated with the synthetic capacity of the intact cells. To prepare the active nuclei the cells were disrupted in hypotonic buffer, the cytoplasm was removed by repeated centrifugation and the nuclei suspended in a suitable buffer. The main drawbacks of this

Fig. 1 A confluent monolayer of BSC-1 cells before (a) and after (b) treatment with 0.5% NP40 25 mM HEPES buffer pH 7.6, 1 mM Mg Cl₂ and 0.5 mM CaCl₂.

Fig. 2 Kinetics of ³H-dTTP incorporation at 37° C. BSC-1 cells were grown to confluence in Eagle's medium in 5 cm Petri dishes and infected at a multiplicity of infection of 10 with HSV type 1 strain α (2×10^7 P.F.U. per 0.2 ml per dish) or mock-infected with 0.2 ml medium. After 1 h the cell sheets were washed twice with 3 ml medium and overlaid with a further 2 ml. At 6 h after infection the medium was removed and 2 ml of cold 0.5% NP40, 1 mM MgCl₂ and 0.5 mM Hepes buffer, pH 7.6 were added. After a minute or two this was decanted and the resulting 'nuclear monolayers' washed with 1.0 ml of the incorporation buffer minus ³H-dTTP (see text), at various pH values. Complete incorporation buffer (0.5 ml) at the appropriate pH was then added to each dish and the dishes incubated in sealed humidified boxes for 45 min at 37° C. The reaction was stopped by adding 2 ml ice-cold 0.15 M NaCl/0.015 M sodium citrate/0.01 M EDTA. The nuclei were scraped off, transferred to tubes, made 0.5% with respect to sodium dodecyl sulphate and heated at 65° for 10 min. After cooling, pronase (500 μ g ml⁻¹) was added and the mixture incubated for 16 h at 37° C. Samples (50 μ l) were taken and the acid-insoluble radioactivity determined by the paperdisk method of Bollum¹³. \times , pH 7.6; \bullet , pH 7.6 but more dNTPs (25 pmol dATP, dCTP, dGTP and 10 μ Ci ³H-dTTP per dish) added after 20 min; +, pH 7.9; \circ , pH 7.1; Δ , nuclei from mock-infected cells, at pH 7.6.

method are that preparation takes at least 30 min, nuclei can be damaged, or lost, due to clumping or rupture during handling and the nuclear pellet is difficult to re-disperse completely.

This report describes a quick and convenient method of nuclear preparation and the results obtained by its application to the study of DNA replication in BSC-1 cells infected with wild-type (wt) and temperature sensitive (*ts*) mutants of herpes simplex viruses. A brief report of the use of similarly prepared 3T3 cell nuclei in the study of RNA transcription has recently appeared¹³.

If BSC-1 cells are treated *in situ*, with the non-ionic detergent NP40 (0.5% in 25 mM HEPES buffer pH 7.6 containing 1 mM MgCl₂, 0.5 mM CaCl₂ and 1 mM dithiothreitol) the cytoplasm is removed, leaving the nuclei and part of the cell membrane firmly attached to the culture vessel as a 'nuclear monolayer' (Fig. 1). Some shrinkage of the nuclei does occur but few are lost and no whole cells are detectable. The nuclear monolayer is stable and can be washed to remove cytoplasmic contamination. Autoradiographic evidence suggests, however, that some ribosomes remain attached to the residue of the cell membrane which surrounds each nucleus.

When BSC-1 cells which have been infected with herpes simplex viruses are treated in this way 5-9 h after infection (when viral DNA synthesis is most active *in vivo*) the resulting nuclei retain a high capacity for viral DNA synthesis. Under the appropriate conditions (50 mM HEPES buffer, pH 7.6, containing 10 mM MgCl₂, 100 mM NaCl, 0.5 mM CaCl₂, 1 mM dithiothreitol, 50 μ M dATP, dCTP and dGTP, 20 μ Ci ml⁻¹ ³H-dTTP and 5 mM ATP, see

Fig. 3 Pycnographic analysis of DNA labelled *in vitro* with ^3H -dTTP in modified incorporation mixtures. *a*, Complete incorporation mixture as described in the text; *b*, complete mixture minus ATP; *c*, complete mixture minus NaCl; *d*, complete mixture but with ATP, CTP, GTP and UTP at $30\ \mu\text{M}$. Incorporation conditions and DNA analysis as described in Figs 2 and 6. The position of virion DNA (....) is also shown in (*a*).

Fig. 2) extensive synthesis occurs. Up to 100 pmol (around 100,000 c.p.m.) can be incorporated per 10^6 nuclei in 60 min at 37°C , and the initial rate of synthesis, during the first 5 min can be as high as $10\ \text{pmol min}^{-1}$. These figures, which are minimum estimates based on the incorporation of added ^3H -dTTP (making no allowance for any endogenous dTTP) compare very favourably with recently published studies in which the techniques of Friedman and Mueller were used to examine the replication of DNA in nuclei from adenovirus KB cells infected with adenovirus type 5^{14,15} and 3T6 cells infected with polyoma¹⁶. Although incorporation falls off fairly rapidly, the addition of more deoxyribonucleoside triphosphates (dNTPs) at 20 min maintains the existing rate for almost another hour (Fig. 2), indicating that a major cause of the reduction in the rate of synthesis is probably lack of substrate; due presumably to degradation. This has not been checked directly.

The addition of more ATP at this time has no effect. This is perhaps to be expected as the ATP concentration in the mixture (5 mM) is already fairly high. Although ATP is required for full activity, a substantial, but variable, amount of incorporation (10–65% of that in the complete mixture) occurs even in its absence. It is not clear whether this is due to residual endogenous ATP or to a DNA synthetic activity which does not require ATP.

If magnesium, or all four dNTPs, are omitted, however, synthesis is reduced to less than 5%. Similarly, if NaCl is not added to the incorporation buffer, synthesis, particularly

of viral DNA (see Fig. 3), is severely inhibited. Dithiothreitol, (the omission of which has little effect) is added as a precautionary measure since the sulphhydryl antagonist N-ethylmaleimide (at 20 mM) completely inhibits DNA synthesis in these nuclear preparations.

Under these conditions nuclei prepared from mock-infected cultures exhibit almost no DNA synthesis (Fig. 2). Since these cells are subject to contact inhibition of growth and movement, and have been confluent for at least 2 d before use, there is little *in vivo* DNA synthesis compared with a logarithmically growing population. The activity detected *in vitro* is, however, considerably lower than would be expected. This may mean that the residual DNA synthesis in resting cells depends on a soluble polymerase which is lost during preparation of the nuclei.

As expected, nuclei from virus-infected cells will incorporate radioactivity from any of the four dNTPs. It is, however, surprising to find that ^3H -TdR is also readily incorporated, provided the other three dNTPs are supplied (see Fig. 4). No incorporation occurs in the absence of ATP, nor can any of the other deoxyribonucleosides be incorporated. This activity is not therefore due to a few whole cells which have survived the detergent treatment. Since these nuclei are washed before assay, it seems that this activity is bound either in, or to, the nucleus, or alternatively, to the remains of the cell membrane.

This observation is of particular interest since it is well established that one consequence of herpes virus infection is the appearance of a virus-specific thymidine kinase^{7,8} shortly before the onset of viral DNA synthesis. In mock-infected cells very little ^3H -TdR is incorporated.

A direct comparison of the absolute amounts of DNA synthesised *in vivo* and *in vitro* in a given time cannot be made without greater knowledge of the many parameters involved (such as pool sizes and rates of synthesis). It is not known whether initiation of new rounds of DNA synthesis occurs *in vitro* or whether those molecules already in the process of replication when the nuclei are prepared are merely completed. Nevertheless, when the DNA synthesised *in vitro* is banded on a CsCl gradient the relative amounts of viral and cellular DNA always reflect the *in vivo* pattern throughout the viral growth cycle (see Fig. 5). Closer examination of the CsCl profiles, however, reveals that the *in vitro* labelled viral DNA appears to consist of several species with slightly different densities, rather than a single homogeneous peak. This heterogeneity (a trace of which can often be seen even in viral DNA prepared from whole cells) is more noticeable

Fig. 4 Kinetics of ^3H -TdR incorporation at 37°C . Cells were infected and nuclei prepared as in Fig. 2. The incorporation protocol was also the same, except that ^3H -TdR ($20\ \mu\text{Ci ml}^{-1}$) replaced dTTP in the incorporation mixture. \times , pH 7.6; \circ , pH 7.1; $+$, pH 7.9; Δ , nuclei from mock-infected cells at pH 7.6.

Fig. 5 Pycnographic analysis of DNA labelled *in vivo* (a and b) with ^3H -TdR, or *in vitro* (c and d) with ^3H -dTTP. At 3 h (a) and 7 h (b) after infection, cells were exposed to ^3H -TdR ($5 \mu\text{Ci ml}^{-1}$ in Eagle's medium) for 45 min at 37°C . The medium was decanted, the cell sheet washed with 3 ml phosphate buffered saline and cytoplasm removed by treatment with 0.5% NP40. The nuclei were scraped off and DNA extracted as described in Fig. 2. Nuclear monolayers were also prepared 3 h (c) and 7 h (d) after infection, labelled with ^3H -dTTP ($20 \mu\text{Ci ml}^{-1}$) for 45 min and DNA extracted as before. ^{32}P -labelled phage T4 DNA was added to the DNA thus obtained and the solutions adjusted to a density of 1.723 g ml^{-3} with CsCl and centrifuged in a Spinco Ti 50 rotor for 3 d at 40,000 r.p.m. Five-drop fractions were collected and the acid-insoluble radioactivity to $50 \mu\text{l}$ samples determined. The bottom of the tube is on the left and viral DNA bands at the denser position.

on some occasions than on others. It is accentuated by omissions from, or additions to, the incorporation mixture (Fig. 3). The various components (probably five in number) seem to occur at fairly consistent densities but in varying amounts and, so far, remain unexplained. Some have buoyant densities greater than virion DNA and others have densities intermediate between virion and cellular DNA. It has not yet been determined which peaks are viral, and which cellular, in origin. They may arise from both sources and exhibit greater buoyant densities due to the presence of RNA sequences and/or some degree of single strandedness. Attempts to distinguish between these possibilities have been unsuccessful. The main 'viral' DNA peak is most affected by the omissions; the host peak much less so. At this stage, however, it is still not clear whether these components are intermediates in viral DNA synthesis or merely artefacts.

DNA synthesis was studied in nuclear monolayers prepared from cells infected with *ts* mutants of HSV type II. Mutants of HSV type I were not used because it was difficult to obtain good titres in these cells. (This problem has now been

largely overcome.) The type II mutants (isolated by Timbury¹⁷ and characterised by Halliburton and Timbury¹⁸ in this Institute) were therefore used, although these have certain drawbacks. The switch off of host cell DNA synthesis is poor, the viral eclipse phase tends to be protracted at the permissive temperature (31°C) and the wt virus itself is slightly inhibited at the non-permissive temperature (38°C).

Cells were infected with either of two mutants of HSV II; *ts5*, a DNA-positive mutant (in which viral DNA synthesis appears to be unimpaired at 38°C) and *ts1*, a DNA-negative mutant (in which no viral DNA is made at 38°C). After 7 h at 38°C , when DNA synthesis in cells infected with *ts5* was known to be proceeding rapidly, both batches of cells were cooled to 31°C and *in vivo* DNA synthesis was measured by a 45 min pulse of ^3H -TdR. At the same time nuclear monolayers were prepared and exposed to ^3H -dTTP for 45 min also at 31°C . The labelled DNA was isolated and banded on a CsCl gradient (Fig. 6). The absolute amounts of radioactivity *in vivo* and *in vitro* cannot of course be compared directly, but the *in vitro* profile mirrors the *in vivo* picture in both cases. Thus, in *ts5* infected cells, where viral DNA synthesis appears to be proceeding normally, it can be detected *in vitro*. In the case of *ts1*, on the other hand, no viral DNA synthesis can be seen, *in vivo* or *in vitro*, in the 45 min following the change to the permissive temperature. This probably means that under these conditions a step essential for the assembly of the synthetic apparatus and initiation of DNA synthesis is blocked and that there has been insufficient time at the permissive temperature for the production of detectable amounts of viral DNA. In contrast to this is the finding (J. Hay, personal communication) that both *ts5* and *ts1* when grown at the non-permissive temperature produce normal (or greater than normal) amounts of the soluble herpes-specific DNA polymerase assayable in extracts of infected cells.

It is, therefore, of particular interest to know whether, in the case of *ts1*, the DNA synthetic apparatus, once it has been established at the permissive temperature, still exhibits temperature sensitivity and whether this is demonstrable *in vitro*.

Cells were infected with *ts1* and maintained at 31°C for 16 h (when the rate of viral DNA synthesis is highest in this

Fig. 6 Pycnographic analysis of the DNA produced *in vivo* (a, b) and *in vitro* (c, d) by *ts* mutants of HSV type II. Cells were infected as described in Fig. 2 with either the DNA-positive mutant *ts5*, or the DNA-negative mutant *ts1*. After absorption, the temperature was raised to 38°C until 7 h after infection when the cells were cooled to 31°C and either labelled for 45 min *in vivo* with (a, b) ^3H -TdR ($5 \mu\text{Ci ml}^{-1}$ in Eagle's medium) or converted to nuclear monolayers and labelled for the same time with (c, d) ^3H -dTTP, as described in Fig. 2. The DNA was extracted and banded as described in Fig. 5.

FIG. 7 Pycnographic analysis of the DNA produced *in vivo* (a, b) and *in vitro* (c, d) by HSV II *ts1* at the permissive and non-permissive temperatures. Cells were infected as described in Fig. 2 with the DNA negative mutant *ts1*. At the end of absorption the temperature was lowered to 31° C until 16 h after infection when whole cells, and nuclear monolayers were labelled for 45 min at 31° C, or raised to 38° C for 10 min and then labelled for 45 min at that temperature. The DNA was extracted and banded as in Fig. 5.

mutant). Whole cells and nuclei were then assayed, at both 31° C and 38° C, for incorporation of ^3H -TdR or ^3H -dTTP respectively. (Fig. 7). The viral DNA synthetic apparatus appears to be quite clearly temperature sensitive *in vivo*. The effect *in vitro*, although always in the same direction, is much less marked. This may well mean that the *ts* function contributes less to the overall rate of DNA synthesis *in vitro* than *in vivo*. These experiments are always difficult to control accurately, because of factors such as variation in the synthetic rates at different temperatures, the effect of temperature on the timing of the viral cycle and differences in pool sizes, such that the changes *in vitro* are to some extent masked by the inherent variability of the system. So, although this technique probably gives rise to nuclei which are capable of temperature-sensitive DNA synthesis *in vitro*, further experiments involving a variety of *ts* mutants will be required to confirm this. In addition several important questions remain unanswered. What is the exact nature of the DNA product? What is the role of cytoplasmic factors? Can reinitiation occur?

Nevertheless, these results establish that to a large extent the DNA synthesis observed *in vitro*, in this system, represents true, although perhaps incomplete, viral DNA replication. This method, which enables the quick and gentle exposure of the site of DNA synthesis in a form accessible to precursors, drugs and enzymes, when used with the many *ts* mutants of HSV types I and II now available, can contribute greatly to the elucidation of the molecular biology of herpes virus replication and the problems of mammalian DNA synthesis.

I thank Mr David Joicey for technical assistance. This paper was first reported at the Society for General Microbiology Virus Group Meeting in London in January 1973 and at the Ninth International Congress of Biochemistry in Stockholm in July 1973.

Multigenic control of ribosomal properties associated with cycloheximide sensitivity in *Neurospora crassa*

It has been shown by McKeehan and Hardesty¹ that, during protein synthesis by 80S ribosomes, cycloheximide selectively inhibits movement of peptidyl-tRNA from the acceptor to the donor site, and that the coupled hydrolysis of GTP, catalysed by the soluble factor T-II in combination with

FIG. 1 Effect of cycloheximide on the poly(U)-directed ^{14}C -phenylalanine incorporation into protein by cell free preparation of wild-type and cycloheximide-resistant mutants of *Neurospora crassa*. Protein synthesis *in vitro* was studied in a mixture containing: 50 mM Tris-HCl, pH 7.8; 2 mM ATP; 1 mM GTP; 2 mM phosphoenol pyruvic acid; 15 μg pyruvate kinase; 20 mM KCl; 10 mM mercaptoethanol; 10 mM magnesium acetate; 50 nCi ^{14}C -phenylalanine, specific activity 400 mCi mmole⁻¹; 20 μg poly(U); ribosomes equivalent to 20 μg rRNA and 75 μg of S-100 protein, in a volume of 0.25 ml. Ribosomes washed once in the extraction buffer were used. \times , Wild type, STA; \circ , CH94; Δ , CH40, two different experiments; \bullet , CH96.

† Threshold concentrations of cycloheximide for inhibition of colony formation on solid medium.

the ribosomes, is not affected. They proposed that cycloheximide might inhibit protein synthesis by occupying sites on the ribosomes usually available for peptidyl-tRNA. As direct association of the T-II catalysed reaction with translocation has not so far been demonstrated, and GTP hydrolysis by T-II is not inhibited by cycloheximide, it is probable that sensitivity to cycloheximide is entirely associated with ribosomes. This was first proposed by Siegel and Sisler² on the basis of species specific differences in the sensitivity to cycloheximide in yeasts and later supported by the work of Wilkie and his associates³. In the latter case a number of cycloheximide resistant mutants have been studied *in vitro*; one of these mutants, having a low level of resistance, seemed to have altered ribosomes.

Resistance to cycloheximide at a high level can result from mutation in any one of at least four genes in *Neurospora crassa*. These genes have different alleles determining different levels of resistance. They are also subject to modification by independent genes⁴. I have investigated three resistant strains, CH94, CH40 and CH96, carrying single gene mutations at the *act-1*, *act-2* and *act-5* loci, respectively, to determine their levels of resistance and the subcellular function which has been modified in each case.

Rapidly collected middle-log phase mycelium, grown from conidia in a New Brunswick Fermentor at 30° C in Vogel's medium⁵, supplemented with 0.1% yeast extract and 2% sucrose, was used for the preparation of the cell free extracts. Preparations of ribosomes and S-100 fractions, as well as assays of the transfer reaction in polyphenylalanine synthesis *in vitro*, were performed essentially as described by Nirenberg⁶. Components of the reaction mixture are indicated in the legend to Fig. 1. Following 10 min incubation at 34° C, 150,000 c.p.m. were detected in hot trichloroacetic acid (TCA)-insoluble material when ribosomes equivalent to 1 mg rRNA were present in the reaction mixture. Dry weight increase in liquid shake cultures during 10 h at 30° C in the presence and absence of cycloheximide, was measured and the % inhibition calculated. Erlenmeyer flasks containing Vogel's medium supplemented with 2% sucrose were inoculated with conidia.

The effect of cycloheximide on protein synthesis *in vivo* was studied in 1 ml samples of 10 h old shake cultures, grown as described above, each incubated at 34° C for 10 min with 20 μ Ci ¹⁴C-phenylalanine, specific activity 10 μ Ci μ mol⁻¹, and cycloheximide. Radioactivity incorporated into protein was measured by the rapid assay system developed by Nirenberg⁶. Sensitivity of growth on solid medium was scored by eye after 2 d incubation at 30° C. Plates, containing Vogel's medium supplemented with 0.3% sucrose, 1% sorbose, and solidified with 2% agar, were spot-inoculated with mycelium.

It is shown in Figs 1 and 2 that in *N. crassa*, mutations in any one of at least three different genes considerably decrease sensitivity to cycloheximide in cell-free extracts, indicating that these genes control components of the protein synthesis apparatus. The effect of cycloheximide on

'hybrid' systems with ribosomes from wild type and supernatant from mutant, or *vice versa*, depends only on the sensitivity of the ribosomal fraction. Thus, the three genes studied in this work control ribosomal components. These mutations are easily scored on agar media because at least a 200-fold increase of cycloheximide concentration is required to inhibit colony formation of the resistant strains in comparison with wild type. Scoring of resistance of growth and *in vivo* protein synthesis in liquid cultures is also easy (Table 1).

It is interesting to notice that in the results obtained in this work the three genes cannot be easily differentiated *in vivo* by level of resistance, in spite of the fact that the decreased sensitivity of all three resistant mutants is clear

Fig. 2 Response to cycloheximide of cell-free systems of ribosomes and supernatant from wild type and three cycloheximide resistant mutants of *Neurospora crassa*. Protein synthesis *in vitro* was assayed in the mixture described in the legend to Fig. 1, except that ribosomes, washed once in the extraction buffer adjusted to 0.5 M NH_4Cl were used. ●, Wild type system; ×, resistant system; ○, hybrid system with ribosomes of the wild type; ⊕, hybrid system with ribosomes of the resistant type.

cut. *In vitro*, the resistant mutants are even less sensitive than *in vivo* and three different levels of resistance can be recognised, though the *in vitro* resistance of strain CH40 is variable.

The genetic control of resistance of cycloheximide in *N. crassa* was first studied by Hsu⁷. Two unlinked genes, *act-1* and *act-2*, located between well defined markers, have been identified. Hsu has shown that both *act-1* and *act-2* are dominant in heterokaryons and that the double-resistant homokaryotic recombinants obtained from *act-1* × *act-2* are characterised by extremely slow growth rate and almost complete insensitivity to cycloheximide.

My work shows that three genes, two of which are those studied by Hsu⁷, control ribosomal properties related to sensitivity to cycloheximide. It is not yet known whether rRNA or ribosomal proteins are the components modified by the three mutations or whether the genes concerned are structural genes for these components or specify modifying factors as in the case of resistance to kasugamycin in *Escherichia coli*⁸. The dominance of mutations at the *act-1* and *act-2* genes, demonstrated by Hsu⁷, is easily compatible with the idea that these genes specify diffusible factors able to transform all ribosomes in heterokaryons to resistance. On the other hand, if these genes control the primary structure of ribosomal components, their occurrence at scattered sites in the genome is against the idea of more than one of them controlling rRNA. Whatever the modified component may be, however, the extremely slow growth rate of the double resistant (*act-1*, *act-2*) homokaryotic recombinant, observed by Hsu⁷, indicates that some essential function other than binding of the antibiotic is supplied by the normal products of these genes, which is only weakly present in the mutants. That this function is translocation is an interesting possibility.

This work was carried out at the Department of Genetics, University of Leeds, while I held a Scholarship from the Greek State Scholarship Foundation. I wish to thank Professor J. R. S. Fincham for his helpful advice, criticism and support during the course of this investigation and also for critically reading this manuscript.

While this paper was being prepared for publication, Pongratz and Klingmüller reported (*Molec. gen. Genet.*, **124**, 359; 1973) that in *N. crassa*, cycloheximide resistant mutants carrying mutations at the genes *act-1* and *act-2* are resistant *in vitro*.

Depression of polymorph counts by various scrapie agents

It has been reported by Carp, Licursi, Merz and Merz^{1,2} that the percentage of circulating polymorphonuclear neutrophils (PMN) in C57Bl mice was reduced permanently following injection with either multiple sclerosis or scrapie tissues. They reported that the decrease was first detected 3 d after injection in the case of scrapie and that the decrease persisted throughout the preclinical phase of the disease: most of their results were from mice bled 6 weeks after injection. We report here the confirmation of some of their findings and also discuss certain difficulties which can arise with this test.

Two inbred strains of mice C57Bl, VM and their F₁ cross were used in one mouse colony (ABRO) and C57Bl in another colony (MRI) in various experiments extending in all over 9 months. In one type several biologically different strains of mouse-passaged scrapie³ were used, in a second sheep and goat scrapie (natural or experimental cases) were used, while in a third an attempt was made to confirm the presence of the PMN factor at titres higher than scrapie infectivity and evidence for its replication was sought. In another series of experiments 22A mouse-passaged scrapie was injected into C57Bl, VM and C57Bl × VM mice as a time sequence study from 42 to 158 d. In all experiments etherised mice were bled brachially for PMN counting 6 weeks after injection, or later in the time sequence study.

In all cases intracerebral injections of male mice were used: with the exception of the titrations, inocula were 10⁻² saline brain homogenates (500g, 10 min supernatant). Brains of the appropriate genotype from normal animals or ones with other neurological diseases were used as control inocula. Because it can be much more difficult to recognise different types of leukocytes in mice than in many other species, especially the recognition of PMN with 'tight' nuclei, all the slides were coded and differential counting done 'blind' by Mrs P. Licursi who had made the original observations.

With six different agents tested in ABRO C57Bl mice (22C, 79A, 87A, 51C, 125A and 139A) the PMN percentages were each significantly lower than in the controls ($P < 0.01$) but with 79V agent tested in VM mice the reduction was not significant. Further work is necessary before the important conclusion could be reached that 79V is not associated with any PMN factor. In the time sequence study with 22A agent there was a reduction in each of the three genotypes of mice at 42, 70, 106, 136 and 158 d and this was significant ($P < 0.02$) in 10 of the 15 groups but there was no PMN change in the three groups at 89 d. With six sources of scrapie from sheep (138A, 141A, 161M, RLE, SSBP/1/21, 161P) and two from goats ('scratching' and 'drowsy' types) there were also significant PMN reductions in MRI C57Bl mice compared with the controls which included a pool of 20 brains from normal sheep and sheep with the Border disease or swayback. In the above work mice from both colonies were used and the C57Bl PMN values in control mice ranged from 12.5 ± 0.45 to $16.8 \pm 0.75\%$ whereas the values in the experimental groups ranged from 4.9 ± 0.79 to $10.6 \pm 0.53\%$. Later work was restricted to C57Bl mice in the MRI colony when normal or ME7-scrapie C57Bl brain was used at dilutions down to 10⁻⁸. These attempts to check whether the PMN factor had a higher titre than scrapie infectivity and whether it replicates, failed because the control mice on this occasion had much lower PMN values (5.7–8.8%) than on the previous occasions and were similar to the scrapie-injected groups (5.2–7.7%). Subsequent checks of PMN counts in the MRI colony in uninjected C57Bl mice also showed similar low values (6.6 to 8.9%).

There are two major features in these results. The general findings confirm and extend to numerous strains of scrapie the report of a factor in scrapie-brain which reduces the

circulating PMN values in mice. There seem to be other unidentified factors, however, which can depress the number of circulating polymorphs for considerable periods of time within a colony. It is probably important that in our earlier group of successful experiments the control C57Bl PMN values were very similar to those reported originally by Licursi *et al.*² It may therefore be necessary for this test to use, as controls, C57Bl mice which have average PMN counts in excess of 12%.

Can energy generated by sugar efflux be used for ATP synthesis in *Chlorella*?

CELLS of *Chlorella vulgaris* can be induced to accumulate hexose analogues more than one thousand fold^{1,2}. This active uptake can be driven by respiration or photosynthesis^{1,3}. During the steady state of 6-deoxyglucose accumulation, (when sugar influx equals sugar efflux) in the dark with air, only about half the influx is powered by respiratory energy and half the steady-state flux rates are still observed under nitrogen^{3,4}. This part of the steady state flux, can, however, be completely inhibited by uncoupling agents such as dinitrophenol or FCCP (ref. 3). It has been postulated, therefore, that about half of the 6-deoxyglucose steady-state influx is supplied with energy generated by efflux.

But can this form of energy, 'efflux energy', only be used for transport into the cell or can other energy requirements of the cells be met by it? For example, the carrier-mediated efflux of ions (Ca^{2+} or K^+) can generate ATP—apparently by the reversal of the energy-dependent influx reaction⁵⁻¹⁷.

To answer this question for *Chlorella* the following experiment was designed. The uptake of glucose and its assimilation is limited by energy under anaerobic conditions in the dark; much higher rates are observed under aerobiosis. When the fate of radioactive glucose in such cells is followed and compared with that of cells preloaded with non-radioactive 6-deoxyglucose, it should be possible to decide if the efflux energy, generated by 6-deoxyglucose leaving the cells, can be used for the ATP-requiring processes of glucose assimilation. *Chlorella* cells were preloaded with unlabelled 6-deoxyglucose until an inside concentration of 0.1 M was reached. These cells were centrifuged and washed with buffer to remove 6-deoxyglucose. Radioactive glucose was added to these cells in anaerobic conditions and the uptake and metabolism of glucose was followed. These data were compared with data obtained with anaerobic cells, not preloaded with 6-deoxyglucose (Fig. 1). Cells not preloaded show a low rate of uptake for glucose of 34 μmol per h per ml packed cells (PC). The glucose taken up is rapidly metabolised; predominantly to glucose phosphate, sucrose and ethanol-insoluble products, which are almost exclusively starch. Hardly any free glucose can be detected.

Cells which were preloaded with 6-deoxyglucose showed a higher rate of uptake (278 μmol per h per ml PC). The rate

of phosphorylation, however, as well as the rate of sucrose and starch synthesis was very similar to that of control cells. Free glucose was considerably accumulated, therefore, and the amount of glucose present after 4 min was clearly higher than the theoretical concentration equilibrium. It has to be emphasised that in no other uptake condition was it possible to observe that *Chlorella* contains a significant amount of free glucose.

The amount of ATP which is required for glucose assimilation is known to be 1 ATP per glucose phosphate, 3 ATP per sucrose and 2 ATP per each glucose incorporated into starch. The ATP utilised for glucose assimilation has been calculated for both experimental conditions and it was found to be identical for non-preloaded cells (51.5 μmol per h per ml PC) and for cells preloaded with 6-deoxyglucose (53.5 μmol h⁻¹ ml⁻¹ PC).

The energy derived from 6-deoxyglucose efflux is quite capable therefore, of driving glucose influx which is increased by a factor 8.18, but it is apparently not able to sustain glucose metabolism by synthesising ATP.

The possibility that 6-deoxyglucose present in the cells prevents the metabolism of glucose, by competitive inhibition for example, has at least been excluded for the hexokinase reaction by *in vitro* experiments.

The results reported here can be explained by the proton symport theory of Mitchell⁹. According to this theory, the proton-translocator movement should be reversible in principle, obeying only the concentration of protons on each side of the membrane. When cells have accumulated high amounts of sugar and the steady state (influx equals efflux) has been reached, protons should also move outward, cotransported with sugar against the proton gradient. In this way sugar efflux would partly restore energy for sugar influx. In addition, any proton gradient, including that created by efflux, could theoretically be transformed to ATP, when a proton dependent ATPase is part of the membrane across which the proton gradient exists. As no additional ATP synthesis has

Fig. 1 Uptake and metabolism of ^{14}C -D-glucose by, a, *C. vulgaris* and, b, by *C. vulgaris* preloaded with 0.1 M 6-deoxyglucose in anaerobic conditions in the dark. Packed cells (PC) 300 μl of induced algae¹, were incubated anaerobically³ in 12 ml 0.025 M sodium phosphate buffer, pH 6.5. The uptake experiment was started by addition of 0.8 μCi ^{14}C -glucose at a final concentration of 5×10^{-3} M. Samples of 2 ml were withdrawn filtered and the cells were extracted in 80% ethanol. The radioactive compounds were separated by paper chromatography and the amounts determined as described previously⁸. The algae used for experiment a did not have detectable amounts of free hexoses inside, whereas the algae for experiment b had been incubated aerobically for several hours in 1×10^{-2} M non-radioactive 6-deoxyglucose and were then centrifuged to remove external 6-deoxyglucose. All experiments were performed in the dark at 27°C. ●, Glucose phosphate; ○, sucrose; △, insoluble; ×, glucose; →, concentration equilibrium.

been observed, however, this indicates that either no such ATPase exists or that it is not able to compete with the uptake systems for protons. A third explanation might be that the energy available is inadequate.

That a proton gradient might really be the driving force for sugar transport in *Chlorella vulgaris* is indicated by recent results. Experiments with energy poisons suggest that a high-energy intermediate of respiration formed before ATP is the relevant metabolite for active hexose transport in *Chlorella*¹⁰. In addition, it has been possible to observe pH change corresponding to a proton symport, when transportable sugars were added to induced *C. vulgaris* cells¹¹.

Implications of rigescent integuments as a new structural feature of some algal chloroplasts

CURRENT concepts concerning the origin of plastids have revived the symbiotic theory of Mereschkowski¹ and Faminzin². Evidence in support of this theory has come from recent work on *in vitro* culture of chloroplasts³⁻⁵. We provide further evidence here by the demonstration of a rigescent integument surrounding the chloroplasts of some siphonaceous algae.

During the preparation of chloroplasts from *Caulerpa sedoides*³, we noted that, in distilled water, there was no swelling or bursting of the plastids as might have been expected. It proved very difficult to break them by any of several methods; they withstood blending in a Waring blender, homogenising in a Ten Broek grinder, freezing and thawing, and sonication. The only method to give quantitative disintegration of the chloroplasts was the French pressure cell used at 8,000 pounds inch⁻².

Detergents such as 0.1% Triton X-100 and Tween 80 had no observable effect on the morphology of the chloroplasts and 1% cetyltrimethylammonium bromide (CTAB) removed chlorophyll only after 48 h and several changes of solution. Sodium dodecyl sulphate (SDS) at 1%, removed chlorophyll and internal lamellae rapidly but left an intact rigescent integument inside which was the intact starch sheath around the pyrenoid (Fig. 1). This integument or 'ghost' withstood boiling in distilled water and centrifugation up to 8000g without any observable change occurring in its structure. It also resisted the action of both pronase and lysozyme.

FIG. 1a. Chloroplast of *Caulerpa sedoides* isolated and resuspended in distilled water. $\times 484.50$ Under phase contrast microscopy. b, A rigescent integument prepared from the chloroplasts of *Caulerpa sedoides* by treatment with 1% SDS. The 'ghost' is without chlorophyll and lamellae but retains a characteristic 'butterfly' shape and an apparently unaltered starch sheath around the pyrenoid. $\times 48450$ Stained with toluidine blue under phase contrast microscopy.

The ghosts were weakly birefringent when examined by polarising microscopy, but scanning electron microscopy showed that they lacked any marked surface features and appeared relatively smooth (Fig. 2). In a related species, *C. cactoides*, transmission electron microscopy and interference contrast microscopy of SDS-treated plastid integuments showed that the terminal body of the plastid, considered by some^{6,7} to be a part of the membranous lamellar system of the chloroplast, appeared to be a coherent and integral part of this integument, and remained attached to it even after treatment with SDS. The role of this terminal structure can be inferred from its behaviour during plastid division, where, early in the formation of the characteristic 'butterfly'-shaped chloroplast, the body seems to divide or duplicate and is thereafter carried in the tip of each 'wing'. This suggests that it is in some way involved in the maintenance of polarity in the chloroplast, which at this stage shows remarkable symmetry and alignment of its lamellar system (Fig. 3). A similar, though smaller and more diffuse terminal body, has been found in the plastids of *C. sedoides*, but its behaviour during division has not yet been followed satisfactorily.

The chloroplast integument has been demonstrated in several species of *Caulerpa* (*C. sedoides*, *cactoides*, and *simpli-cuiscula*) and raises the problem of its possible function. Many saccoglossan opisthobranchs eat species of siphonaceous algae almost exclusively and the primitive forms seem to prefer species of *Caulerpa*⁷. It seems possible that the rigescent integument around the chloroplasts of some of these

FIG. 2 Exterior surface of rigescent integument of *Caulerpa sedoides* chloroplast as seen with the scanning electron microscope. The surface appears smooth. $\times 5,700$. b, A rigescent integument of *Caulerpa sedoides* chloroplast which was broken during preparation for scanning electron microscopy to reveal not only the starch sheath around the pyrenoid inside the integument (arrowed) but also the 'ghost-like' nature of the integument. The small bodies adjacent to the integument are amyloplasts. $\times 5,700$.

Fig. 3a. An *in vivo* plastid of *Caulerpa cactoides* apparently before division, with the terminal swellings of the integument positioned at the tips of the 'butterfly wings' creating two axes of polarity in the lamellae. $\times 207,480$. b, A chloroplast of *Caulerpa cactoides* showing the remarkable symmetry of lamellae just before division. $\times 2,109$.

species protects them from digestion in the gastric juices of the animal and may be of some selective value in ensuring endosymbiosis in animal tissue.

The discovery of these integuments, however, has a bearing on the endosymbiotic theory of the origin of chloroplasts. Not only do these plastids have an integument which endows them with physical resistance to external conditions, they are also capable of repeated division outside the cell^{4,5}, and have photosynthetic pigments closely related to those of normal green algae and higher plants⁸. The resistance of the integument to the action of lysozyme shows a significant difference from the cell wall material characteristic of the blue-green algae, which have been considered the prime contenders for the role of the primitive chloroplast ancestors. It seems that the plastids of some siphonaceous algae may represent either a missing link in the development of plastids from the ancestral algal symbiont, or an alternative line of plastid evolution.

Molecular conformation of deoxyguanosine 5'-phosphate

THE allowed conformations of nucleic acids depend on the flexibility of the structure of the nucleotides from which they are constructed. Many X-ray crystallographic studies of the degree of flexibility of these structures have shown that nucleosides exhibit a larger number of preferred conformations than nucleotides, and this led Sundaralingam¹

to suggest that a nucleotide is more 'rigid' than a nucleoside. Berthod and Pullman², however, have drawn attention to the fact that considerations of conformational energy do not imply such a rigid structure.

We have recently determined the crystal structure of the disodium salt of deoxyguanosine 5'-phosphate tetrahydrate (GDRP), and we find that the pucker of the sugar ring and also the conformation about the C(4')-C(5') bond are different from those found in other 5'-nucleotides which are normal components of DNA and RNA. These results indicate that a nucleotide may not be as rigid as previous crystallographic studies have implied.

Crystals of GDRP were obtained by evaporation from aqueous solutions. The unit cell is monoclinic with $a = 5.56$, $b = 10.76$, $c = 15.77$ Å, $\beta = 97.9^\circ$, and the space group is P2₁. The structure was solved by Patterson interpretation methods. The positions of the phosphorus atom and one of the sodium atoms were determined from the Harker section, and the orientation of the phosphate group was found by means of a rotation function. Successive Fourier syntheses revealed the positions of the remaining atoms. Details of the structure determination will be given elsewhere. The R factor at the present stage of refinement is 0.06.

The conformation of GDRP about the glycosidic bond C(1')-N(9) is *anti*, with the torsion angle O(4')-C(1')-N(9)-C(4) of 237° . In having the *anti* conformation, GDRP is similar to all other nucleotides in the crystalline state and similar to the majority of nucleosides.

The pucker of the sugar ring is unusual in that relative to the mean plane through the five atoms of the ring, atom O(4') has maximum deviation of 0.25 Å *endo* and atom C(4') has the next largest deviation of 0.21 Å *exo*. This type of pucker has not previously been observed in nucleotides, although it has been observed in the nucleoside dihydrothymidine³.

The conformation about the C(4')-C(5') bond in GDRP is also unusual in that the orientation of the C(5')-O(5') bond relative to the C(4')-O(4') and C(4')-C(3') bonds is *gauche-trans*, with the torsion angle O(5')-C(5')-C(4')-O(4') = 62.6° and O(5')-C(5')-C(4')-C(3') = 175.4° . In all other 5'-nucleotides which are normal components of DNA and RNA, and also in all the refined double-helical models of DNA and RNA, the conformation is *gauche-gauche*. The only nucleotide reported with a *gauche-trans* conformation is 6-azauridine 5'-phosphate (ref. 4), which is not a normal nucleic acid component. Amongst nucleosides, however, the *gauche-trans*, as well as *trans-gauche*, conformations occur quite frequently, but the fact that they had not been observed in nucleotides and dinucleotides was one of the reasons why Sundaralingam suggested that a nucleotide is more rigid than a nucleoside.

The chemical structure of deoxyguanosine 5'-phosphate.

The conformational parameters of GDRP suggest that, depending on the environment, conformations other than *gauche-gauche* are possible about the C(4')-C(5') bond. Indeed, in the study of the binding of nucleotides to lactate dehydrogenase⁵ and to staphylococcal nuclease⁶, the *gauche-trans* conformation is required in order to explain the difference-Fourier maps, and a similar conformation is proposed for a dinucleotide phosphonate when it binds to RNase-S (ref. 7). The present results may also make possible models of single-stranded viral nucleic acids with conformations other than *gauche-gauche*. Finally, it is worth noting that the original Watson-Crick model of DNA⁸ had a *gauche-trans* conformation about the C(4')-C(5') bond, although it was a feature which required modification to *gauche-gauche* in order to fit the X-ray diffraction data⁹.

Rosette formation by a mouse fibroblast cell line

THE properties and activities of mammalian cell membranes have become an area of increasing interest in cell biology, and their study has involved a variety of experimental approaches. The mutual interaction of membranes from identical or different cell types has often been studied. For example, it has been found that a large proportion of human peripheral blood lymphocytes, when mixed with sheep red blood cells, form cell clusters known as rosettes, in which a central lymphocyte is partially or fully surrounded by red cells¹⁻³. This also occurs with human thymocytes⁴, and is apparently a property of human lymphocytes derived from the thymus (T cells)^{5,6}.

During the course of experiments designed to study the presence of receptors for antigen-antibody complexes on tumour cells⁷, it was found that the mouse fibroblast cell line, A9, made rosettes to sheep erythrocytes which were not coated with antibody. Here we present experiments describing this phenomenon in A9 cells and in cell hybrids between A9 and TLX/5 tumour cells.

Various cultured cell lines were used in this study: (1) A9, a line which lacks guanylic acid-inosinic acid pyrophosphorylase and was originally isolated by Littlefield as a clone of mouse L fibroblasts resistant to 3 μ g ml⁻¹ of 8-azaguanine⁸. (2) TLX/5, which was derived from a mouse lymphoma⁹ and grown *in vitro*. (3) Three hybrid clones,

resulting from the Sendai virus-induced fusion of A9 and TLX/5 cells *in vitro*. The cell fusion procedure used was essentially that of Davidson¹⁰. The hybrid nature of these cells was confirmed by karyotype analysis. (4) Normal mouse fibroblasts, obtained from secondary cultures of newborn mouse brain. (5) Human skin fibroblasts; (6) A3 hamster fibroblasts obtained from cell lines grown *in vitro* for many generations. The cells used were grown on Falcon plastic Petri dishes in Dulbecco's modified Eagle's medium supplemented with 10% foetal calf serum and 100 IU ml⁻¹ of penicillin, and incubated at 37° C in a humidified atmosphere of 10% CO₂ in air¹¹. Cells were collected from the plates with a rubber policeman and washed twice in gelatin veronal buffered saline (GVB)¹², before being made up to 20 \times 10⁶ cells ml⁻¹ in GVB (other media such as TC199 have been used with similar results).

Red blood cells were obtained from guinea pig, hamster, horse, human, mouse, rabbit, rat and sheep, usually by collecting whole blood in citrated GVB and washing at least three times. 100 μ l of packed red blood cells were added to 10 ml of GVB, which gave a count of approximately 200 \times 10⁶ erythrocytes ml⁻¹ (this was found to be optimum for rosette formation).

0.05 ml (1 \times 10⁶ cells) of the cultured cell suspensions were added to 1 ml of red blood cells in a round-bottomed 5 ml plastic test tube. The cells were mixed and spun down immediately at 150g for 7 min, after which they were resuspended by gently rocking to and fro. 0.33 ml of 2.5% glutaraldehyde in PBS was added to each tube and carefully mixed up to fix the cells¹³. One drop of this suspension was dropped on to a clean slide and allowed to dry. After fixation in methanol, the slides were stained in Leishman's stain and the dried preparations were read¹⁴. In reading the slides, three classes of cells were distinguished; full rosettes were cells which were completely surrounded by erythrocytes, partial rosettes, cells having three or more erythrocytes but were not full rosettes, and non-rosette-forming cells which had no erythrocytes, or one or two, adhering to their surface. Results are expressed as the percentage of these three types.

Table 1 shows the rosette formation of A9 cells with various species of erythrocytes. It can be seen that A9 cells form many rosettes with horse, sheep and hamster, fewer with rat and hardly any at all with the other species tested.

As horse erythrocytes seemed to give more full rosettes than either of the other species tested, we decided to see if any of the other cell lines made rosettes with them. Table 2 shows the results. It can be seen that the only cells which formed any appreciable number of rosettes with horse erythrocytes were A9 and Hybrid C. Two of the hybrids were negative as was the other parental type (TLX/5) and the other cell types tested. This experiment has been repeated using sheep erythrocytes instead of horse erythrocytes with essentially the same results.

The A9 rosettes are sensitive to previous incubation with 0.1% trypsin, or heat killing (56° C, 15 min), but relatively

TABLE 1 Rosetting capacity of A9 cells with various species of erythrocyte

Human skin fibroblasts	0	0	100	0
Mouse brain fibroblasts	0	6	94	6
A3 hamster fibroblasts	0	0	100	0

insensitive to previous incubation with high concentrations of sodium azide.

Many questions are posed by this work. First, since there is a large overlap of cells binding sheep, horse and hamster erythrocytes, is the receptor on the A9 cells responsible for this binding a single receptor, or are there different receptors for sheep, horse and hamster erythrocytes on the same cell?

Second, although A9 cells form rosettes whereas TLX/5 cells do not, only one out of the three hybrid cell lines formed rosettes. One explanation could be that some A9 cells never express the receptor and these were the cells that fused with TLX/5 to form the two negative hybrids. This seems unlikely since the A9 cell line was isolated as a single clone in 1963, and has been cloned several times since then. Another explanation could be that the spatial arrangement of this receptor on the cell surface is critical for red cell attachment. Yet another explanation is that the gene controlling receptor production in A9 was lost during or after fusion with TLX/5, and a corollary to this is that there might be a gene which suppresses receptor production in TLX/5, and that it was this gene which was lost, thus allowing at least one hybrid to show rosette formation. Further observations on the karyotypes of these hybrids should yield information on the possibility of any chromosome loss. The explanations posed above assume that these rosette-forming cells have specific or fairly specific receptors on their surface. The possibility does exist however that rosette formation may be explained by a non-specific phenomenon relating to the physiological conditions of the cells at the time of collection.

Although the A9 cells and one hybrid are the only cells shown here capable of forming rosettes, it might be possible to find other surface markers that are characteristic of certain cell types, such as the lymphocyte in man which binds sheep erythrocytes¹⁻³; this has been suggested as a marker for thymus-derived cells⁵⁻⁶, and is now used routinely in the assessment of T cell function in man¹⁵.

Antibody coated erythrocytes as a manifold probe for antigens

A variety of antigens can be coupled to erythrocytes and these antigen coated erythrocytes (Ag-E) are widely used for the detection of the corresponding antibody¹. In principle, if erythrocytes were coated with antibody, these antibody-coated erythrocytes (Ab-E) would be useful for the detection of the corresponding antigen. Ag-E and Ab-E should exhibit parallel reversed immunological phenomena, for example, whereas Ag-E are agglutinated and lysed by antibody, Ab-E should be agglutinated and lysed by antigen; whereas Ag-E

FIG. 1. Disks of haemolysis produced by human immunoglobulin diffusing into gel containing anti-human immunoglobulin Ab-E. Eleven milliliter of 1% Ab-E and 0.8% agarose in saline borate buffer were allowed to gel in a 10 cm Falcon Petri dish. Five μ l of human IgG diluted in normal rabbit serum (NRS) absorbed with sheep erythrocytes were placed in punched wells. The dish was kept at 4° C for 48 h, then incubated with 4 ml of 1:100 dilution of rabbit anti-human Ig antiserum at 4° C overnight and finally treated with 4 ml of 1:10 dilution of guinea pig complement at 37° C for 2 h. The concentrations (μ g/ml) of human immunoglobulin in the wells are indicated in the photograph.

TABLE 1 Immunoglobulin allotype (antigen)-induced agglutination of sheep erythrocytes coated with antibody specific for rabbit kappa chain allotypes

Indicator cells	Antigen	Antigen dilution (\log_{10})								
		-1	-2	-3	-4	-5	-6	-7	-8	-9
Anti-b4 Ab-E	b4 serum	-	-	+	+	+	+	+	+	-
	b5 serum	-	-	-	-	-	-	-	-	-
	b4b5 serum	-	-	+	+	+	+	+	±	-
	b4 IgG (10 mg ml ⁻¹) ₄	-	-	+	+	+	+	+	+	-
	b4 serum + anti-b4*	ND	ND	ND	ND	-	-	-	-	-
Anti-b5 Ab-E	b4 serum	-	-	-	-	-	-	-	-	-
	b5 serum	-	-	+	+	+	+	+	+	-

The antigens were absorbed with sheep erythrocytes and serially diluted with 0.2% gelatin in 0.15 M NaCl. Then, 0.1 ml of the dilutions was incubated with 0.1 ml of 1% indicator cells (Ab-E) in 0.15 M NaCl at 4° C overnight.

* 0.1 ml of the dilution of b4 serum was incubated with 5 μ l of anti-b4 antiserum at 37° C for 30 min before incubating with the Ab-E.

are antibody reactive, Ab-E should be antigen reactive. To test this prediction, we attached various antibodies, purified from antisera by using immunosorbents², to sheep erythrocytes by the chromium chloride method³. These Ab-E were tested with the corresponding antigens by agglutination, haemolysis and immunocytoadhesion methods.

Erythrocytes were coated with the following purified antibodies: goat anti-rabbit immunoglobulin, goat anti-rabbit α_2 -macroglobulin, rabbit anti-bovine serum albumin (BSA), rabbit anti-mouse immunoglobulin, rabbit anti-human immunoglobulin and rabbit antibodies to various rabbit immunoglobulin allotypes (b4, b5, a1, a2 or a3). These Ab-E were incubated with serial dilutions of the corresponding antigens. In all instances, the antigen agglutinated the erythrocytes coated with the antibody specific for the tested antigen. For example (Table 1), in the system with the rabbit b4 immunoglobulin as antigen and anti-b4 Ab-E as indicator cells, rabbit serum or purified IgG having the b4 antigenic determinants agglutinated anti-b4 Ab-E, whereas b5 serum did not. Similarly, b5 serum, but not b4 serum, agglutinated anti-b5 Ab-E. Moreover, anti-b4 antiserum inhibited the agglutination of anti-b4 Ab-E induced by b4 molecules. This antigen-induced agglutination of Ab-E was characterised by a prozone in antigen excess and by end-points at antigen concentrations as low as 1 ng ml⁻¹ or lower (Table 1). In addition, b4 IgG-E and anti-b4 Ab-E co-agglutinated when incubated together, whereas no agglutination was obtained when b5 IgG-E were incubated with anti-b4 Ab-E (not shown).

Ab-E were first treated with the corresponding antigen, then with antibody specific for the bound antigen and finally with complement. The reaction with the corresponding antigen made the Ab-E sensitive to lysis. Thus, anti-b4 Ab-E lysed when sequentially treated with b4 IgG, anti-b4

Fig. 2 Haemolytic plaques formed by human lymphocytes with antihuman immunoglobulin Ab-E. Lymphocytes, isolated from blood of a healthy individual by the Ficoll method⁸ were washed with Hanks solution and tested with anti-human immunoglobulin Ab-E by the PFC assay⁵. After incubation at 37° C for 1 h, the dishes were treated with rabbit anti-human immunoglobulin antiserum and guinea pig complement as described in Fig. 1.

antiserum and complement (Table 2). The lysis was specific.

A useful application of this antigen-mediated lysis of Ab-E is the quantitation of antigen by single radial immune haemolysis in gel. When human immunoglobulin at known concentrations was allowed to diffuse from wells into agar gel containing anti-human immunoglobulin Ab-E, localised haemolysis developed around the wells upon addition of rabbit anti-human immunoglobulin antiserum and complement (Fig. 1). At low antigen concentrations, the area of these haemolytic circles, after 48 h, was proportional to the concentration of the antigen. This single radial immunohaemolysis method is a modification of Mancini's method⁴, the major difference being that the antibody is immobilised in the gel by anchorage to the E and the major advantage being that the sensitivity (0.1 μ g ml⁻¹) is greater.

The most important practical use of the antigen-mediated lysis of Ab-E is the detection and enumeration of antigen-secreting cells by an unprecedented PFC (plaque forming cell) assay. In all other PFC assays an antigen either native⁵ or artificial⁶ on the membrane of the erythrocyte is the target for the antibody secreting cells. If Ag-E can detect antibody-secreting cells, Ab-E should detect antigen-secreting cells. More specifically, whereas erythrocytes coated with BSA are an indicator for anti-BSA antibody-secreting cells, anti-BSA Ab-E should be an indicator for BSA-secreting cells. We have indeed found that normal human peripheral lymphocytes formed haemolytic plaques when assayed with anti-human immunoglobulin Ab-E (Fig. 2). Being based

TABLE 2 Immunoglobulin allotype (antigen)-mediated lysis of sheep erythrocytes coated with antibody specific for b4 light chain allotype

Indicator Cells	Antigen	Developing Antiserum	Lysis
anti-b4-E	b4 serum	anti-b4	+
	b4 serum	—	—
	b4 IgG	anti-b4	+
	b4 serum	anti-b9	—
	b9 serum	anti-b4	—
uncoated erythrocytes	b4 serum	anti-b4	—

Two ml of 1% Ab-E and 0.8% agarose in 0.15 M NaCl were allowed to gel in a 60 mm plastic Petri dish. All the sera were absorbed with sheep erythrocytes and serially diluted. A droplet of each serial dilution of antigen was placed on the gel and allowed to be absorbed. Then 2 ml of a 1:100 dilution of developing antisera were added. After overnight incubation at 4° C the developing reagent was decanted and 1 ml of a 1:10 dilution of guinea pig complement was added. The dishes were then incubated at 37° C for 1 h. The lowest concentration of b4 IgG, still mediating lysis of the Ab-E, was 1 μ g ml⁻¹.

TABLE 3 Rabbit lymphocyte surface immunoglobulin allotypes detected by rosette formation with sheep erythrocytes coated with antibody specific for the b4 and b5 kappa chain allotypes

Rabbit # and genotype	Indicator cells	Inhibitor*	Rosette forming cells (%)
M302 b ⁴ b ⁴	anti-b4-E	—	22
	anti-b5-E	—	0
M341 b ⁴ b ⁵	anti-b4-E	—	2
	anti-b5-E	—	38
	anti-b5-E	b4 serum	33
	anti-b5-E	b5 serum	4

	anti-b5-E	anti-b5 antiserum	6
	uncoated-E	—	1

Lymphocytes isolated from heparinised blood by the Ficoll method⁸ were washed thrice with saline, and resuspended to 3×10^6 cell ml⁻¹. Then 0.1 ml of the cell suspension was incubated with 0.1 ml of 1% Ab-E saline containing 0.2% gelatin and 0.05 M NaN₃ at 4° C overnight. Rosetted and nonrosetted lymphocytes were counted in a haemocytometer.

* Inhibitor (5 µl) was added to the cell suspension (0.1 ml) before the addition of Ab-E.

on the antigenic properties of the secreted Ig, the assay can be applied to the enumeration of sub-populations of Ig-secreting cells by exploiting the isotypic, allotypic or idiotype antigenic determinants; for example, allotype secreting cells were enumerated by using erythrocytes coated with the appropriate anti-allotype Ab-E⁷. These immunoglobulin antigen-secreting cells were found in unimmunised individuals, whereas conventional PFC are found only in immunised individuals. Thus, in our PFC assay, an immunoglobulin-secreting cell formed a haemolytic plaque independently from the antibody specificity of the secreted immunoglobulin. This antigen-mediated PFC assay has some distinctive features compared to the conventional antibody mediated PFC assay: (1) the target on the erythrocytes is an antibody rather than an antigen; (2) the lysis of the erythrocytes is mediated by antibody rather than antibody; (3) the cell producing the haemolytic plaque need not be an antibody-secreting cell. Cells other than lymphoid can be tested for secretion, provided that the secreted substance is antigenic. Therefore, this new PFC assay is theoretically a general method for detecting antigen-secreting cells, regardless of the cell type. The method differs from the cytochemical and cytoimmunochemical methods in probing for secretion rather than intracellular presence of antigen.

FIG. 3 Microscopic photograph of a rosette formed by a b4 lymphocyte with anti-b4 Ab-E. See Table 3 for experimental details.

Peripheral lymphocytes from homozygous b4 or b5 rabbits were incubated with anti-b4 or anti-b5 Ab-E (Table 3). Lymphocytes from a b4 rabbit rosetted with anti-b4 Ab-E (Fig. 3), but not anti-b5 Ab-E. *Vice versa*, b5 lymphocytes rosetted with anti-b5 Ab-E but not anti-b4 Ab-E or uncoated E. Moreover, this rosette formation of b5 lymphocytes with anti-b5 Ab-E was inhibited by b5 (but not by b4) serum by blocking of the anti-b5 combining sites on the erythrocytes. A similar inhibition was induced by anti-b5 antiserum by masking of the b5 specificities on the lymphocytes (Table 3). The rosetting of antigen bearing cells with Ab-E is a direct simple method for the detection of cell surface antigens and for the enumeration of antigen bearing cells.

In conclusion, we have artificially coupled to erythrocytes various purified antibodies. The specificity of the antibody bound by erythrocytes was retained, as shown by the reactivity of these Ab-E with the corresponding antigen either in soluble form (antigen-induced agglutination and antigen-mediated lysis of Ab-E) or bound to the cell surface (rosette formation with Ab-E). Therefore, Ab-E is a probe for antigen. Accordingly, we have shown that Ab-E can be used in new methods for (1) semi-quantitation of antigen by agglutination, (2) quantitation of antigen by single radial immunohaemolysis (manuscript in preparation), (3) enumeration of antigen secreting cells by a PFC assay⁷, (4) enumeration of cells bearing surface antigen by an immunocytoadhesion method⁷. The same preparation of Ab-E can be used for all of these assays.

Inheritance of a recombinant HL-A haplotype and genetics of the HL-1 region in man

THE major histocompatibility system of man, designated HL-1, includes a series of closely linked genes of diverse functions¹. HL-1 includes loci controlling two closely linked genes for the segregant series of HL-A antigens, genes responsible for the stimulation in mixed lymphocyte reactions (MLR-S) and possibly a genetic determinant(s) important for the induction of delayed-type hypersensitivity responses (HDR)^{2,3}. Recombination between the genes for HL-A and between HL-A and MLR-S has been reported^{2,3}.

HL-A types and mixed lymphocyte culture reactions of a Caucasian family (designated Hea) reported here provide further information on the relationship between genes in the HL-1 region. The transmission of a recombinant HL-A type

* Mean of triplicate determinations of ³H-thymidine uptake by a mixture of 1 × 10⁶ responding and 1 × 10⁶ mitomycin-treated stimulating cells.

† In the negative controls R is the mean of triplicate cultures in c.p.m. of radioactive thymidine uptake of 1 × 10⁶ lymphocytes cultured alone for 120 h. S is the mean of triplicate cultures in c.p.m. of radioactive thymidine uptake of 1 × 10⁶ lymphocytes treated by mytomycin and cultured alone for 120 h.

Enclosed in the rectangle are the values obtained from the reactions of three siblings from the Hea family and one of the unrelated individuals. The low values obtained in those interactions contrast with the stimulation given by other family members.

from the propositus to her progeny confirms the existence of crossing over between the two *HL-A* loci. The MLR reactions between the recombinant and her siblings furnish additional examples of the importance of differences at the second *HL-A* locus for stimulation in mixed lymphocyte culture. Also, the MLR reactions of family Hea provide three examples of strong stimulation between phenotypically identical pairs of subjects, with each pair having one chromosome identical by descent, and presumptive evidence for genetic control of the level of stimulation with cells from an unrelated subject.

HL-A antigens were detected with a standard two-stage, dye exclusion microcytotoxicity test⁴ using 115 well characterised antisera able to detect all defined *HL-A* and most *W* specificities. Tests were repeated at least three times and *HL-A* haplotypes were assigned by conventional methods². Lymphocytes were collected from the subjects into heparinised (25 U ml⁻¹) Pyrex tubes. Part of the sample was transported to the laboratory as whole blood, and part was diluted with an equal quantity of Eagle's minimal essential medium (MEM) and later divided into two fractions which were processed separately. The MLR were carried out as previously described⁵ in triplicate on each of the three cell samples. The final culture volume of 0.2 ml contained 1 × 10⁵ responding and 1 × 10⁵ (mitomycin-treated) stimulating lymphocytes. After 120 h of incubation, cultures were labelled for 18 h with 0.5 μCi ³H-thymidine (New England Nuclear Corp., NET-027 ³H-thymidine-methyl, (NEN) 1.00 mCi ml⁻¹, specific activity 6.10 mmol⁻¹, 0.036 mg). Cells from all donors survived handling when transported as whole blood. When shipped diluted in MEM, cells from one donor were unresponsive, but the others were reactive. Agreement between results of the various fractions, with this one exception, was excellent. The complete data obtained with cells from whole blood are presented in Table 1. The family studied consisted of sixteen members in three generations. Red cell typing gave no evidence of mixed paternity.

The *HL-A* genotypes of the three generations (Fig. 1) show several interesting features. (1) Subject II 3 gave evidence of recombination within the maternally derived haplotypes 3-7/2-12; the recombinant *HL-A* 2-7 haplotype was transmitted to subject III 3. (2) Lymphocytes from the recombinant (II 3) failed to stimulate unidirectional MLR with cells from siblings II 5 and II 7 who differed from her with respect to first segregant series marker *HL-A* 3 (Table 1). Conversely there was stimulation with cells from subject II 1, who differed with respect to the second series marker *HL-A* 12. (Siblings II 5, II 7 and II 1 all share the paternal 11-7 haplotype with II 3 but differ from her in having intact maternal 3-7 or 2-12 haplotypes from which the recombinant was derived.) (3) Lymphocytes from an unrelated subject (DK) stimulated feebly in two tests and failed to

stimulate in the third test with cells from the three MLR identical sibs II 3, II 5 and II 7, while stimulating adequately with all other family members tested. (4) Stimulation developed between subject I 1 (the father) and his phenotypically identical children II 5 and II 7. Stimulation was also observed between the mother I 2 and her phenotypically identical child II 4. To distinguish the *MLR-S* alleles in the *HL-1* haplotypes of the first generation, designations *v*, *x*, *y* and *z* are given in Fig. 1. Alleles introduced in the second generation are not so distinguished. The transmission of the first generation haplotypes can be readily traced.

To explain the strong stimulation observed between a pair of siblings who were genotypically identical for *HL-A*, Plate *et al.* suggested the existence of a locus outside the *HL-A* region and separable from it by recombination⁶. Yunis *et al.* identified another family in which an individual stimulated with his *HL-A* identical sibling^{2,7}. Analysis of the reactions of several families, each including a known recombinant between two segregant series of *HL-A*, showed that stimulation was consistently associated with differences at the second series and not with differences at the first series^{2,8,9}. The recombinant in the family we have reported stimulates with

HL-1 Haplotypes of the Hea Family

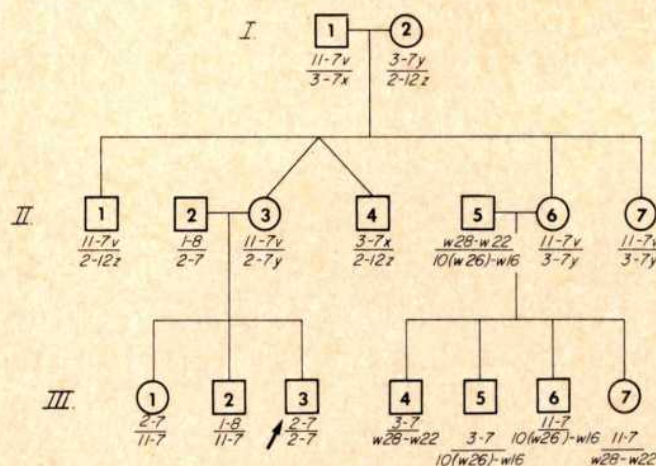

FIG. 1 *HL-1* haplotypes of the Hea family. *HL-1* haplotypes refer to the chromosomal region including two *HL-A* loci, and one *MLR-S* locus (*v*, *x*, *y* and *z*). The hypothetical *HDR* locus is not shown in the pedigree. The arrow identifies the individual to whom the *HL-A* recombinant was transmitted. Numbers under each member of the family represent *HL-A* antigens; the *W* specificities are in conformity with the terminology adopted at the fifth histocompatibility workshop¹¹.

cells from a sibling differing at the second series locus but fails to stimulate with either of the siblings who differ at the first series region. These findings are consistent with the hypothesis that the gene responsible for lymphocyte stimulation, *MLR-S*, is close to the second locus. If this is correct, one would expect the *HL-A* markers to be a poor guide to stimulation in MLR, since the serological tests for *HL-A* do not identify the hypothetical *MLR-S* product. During evolution of the histocompatibility system, recombination between *HL-A* and *MLR-S* should result in a state of equilibrium between the two systems. Therefore, phenotypically identical unrelated individuals would be expected to stimulate frequently, as indeed they usually do². Conversely, one would expect occasional non-stimulation between unrelated subjects regardless of their *HL-A* phenotypes. This family provides three examples of stimulation between phenotypically identical pairs and three examples of non-stimulation or minimal stimulation between phenotypically distinct pairs. One of the individuals (DK) giving minimal stimulation is unrelated, but the pattern of response to her cells correlates with the segregation of the *MLR-S* region of the *HL-1* in the family.

Initiation of protein synthesis during lymphocyte stimulation

THE stimulation of protein synthesis that accompanies the activation of peripheral blood lymphocytes by phytohaemagglutinin (PHA) has been shown to be due largely to an increase in the rate of initiation of protein synthesis¹. Such an increase could result from either an increase in the availability of initiation factors or of mRNA. This problem can be approached most directly by comparing the ability of cell-free protein synthesising systems from stimulated and

unstimulated lymphocytes to form initiation complexes with ³⁵S-methionyl-tRNA^{Met}. Such studies in reticulocytes have shown that the limitation of initiation occurring during haemin deprivation is accompanied by a marked reduction in the number of methionyl-tRNA-40S ribosomal subunit complexes present, and enabled the elucidation of the mechanisms involved^{2,3}. We show here that the binding of ³⁵S-methionyl-tRNA^{Met} to both 40S subunits and 80S ribosomes is increased after activation of lymphocytes by PHA. These differences can be overcome by the addition of initiation factors from reticulocyte ribosomes, but not by the addition of exogenous globin mRNA.

Lymphocytes were purified from defibrinated pig blood by sedimentation with dextran, filtration through cotton wool to remove phagocytes and centrifugation on ficoll-hypaque step gradients to remove residual erythrocytes. The lymphocytes were cultured at 2×10^6 ml⁻¹ in Eagle's minimal essential medium supplemented with 10% autologous serum. Incubation was for 20-24 h at 37° C, either with or without 3 µg ml⁻¹ purified PHA.

To prepare cell-free extracts, the cells were collected by centrifugation and resuspended at 10^9 ml⁻¹ in 10 mM KCl; 20 mM Tris-Cl pH 7.5; 1.5 mM Mg acetate for 10 min at 4° C. They were disrupted with 10 strokes of a Potter homogeniser. The ionic concentration was adjusted to 80 mM KCl; 25 mM Tris-HCl pH 7.5; 4 mM Mg acetate; 6 mM mercaptoethanol (TKM medium), and the homogenate was centrifuged at 6000g for 6 min. The supernatant was passed through Sephadex G25 equilibrated with TKM medium.

³⁵S-methionyl-tRNA^{Met} was prepared by incubation of discharged rabbit reticulocyte tRNA with ³⁵S-methionine

Fig. 1 Effect of globin mRNA on initiation complex formation by extracts from lymphocytes incubated with (b) or without (a) PHA for 24 h. Cell free extracts containing 37 µg RNA were incubated at 30° C for 5 min in 0.2 ml TKM medium supplemented with 1 mM ATP, 0.2 mM GTP, 4 mM creatine phosphate, 0.5 mg ml⁻¹ creatine phosphokinase, a mixture of 19 amino acids excluding methionine, each at 20 µM, and ³⁵S-methionyl-tRNA^{Met} (36,000 c.p.m.). Each incubation was then layered onto a 10-30% sucrose gradient in TKM and centrifuged in the SW 50-1 rotor at 49,000 r.p.m. for 1.75 h. Twenty-six to twenty-eight fractions were collected from each gradient and 1 ml of 2% cetyltrimethylammonium bromide and 1 ml of 0.5 M sodium acetate pH 5.2 containing 0.5 mg ml⁻¹ yeast RNA were added to each. The precipitates were collected on glass fibre filter disks and the radioactivity in each determined. —, Without globin mRNA; ···, with globin mRNA.

Fig. 2 Effect of reticulocyte initiation factors on initiation complex formation by extracts from lymphocytes incubated with (b) or without (a) PHA for 24 h. The composition of incubation mixtures was as for Fig. 1, except that each contained 19 μ g extract RNA, 72,000 c.p.m. 35 S-methionyl-tRNA Met and, where indicated, 25 μ g reticulocyte initiation factors. Incubation was at 37° C for 2 min. The sucrose gradients included a cushion of 2 M sucrose, and centrifugation was at 42,000 r.p.m. for 2 h. —, Without initiation factors; ---, with initiation factors; ···, with initiation factors and globin mRNA.

and activating enzymes from *E. coli*⁴. Methionyl-tRNA Met is not charged under the conditions used. Globin mRNA was prepared as previously described^{6,6}. Initiation factors were extracted from reticulocyte polyribosomes as described by Schreier and Staehelin⁷. The fraction used was that which eluted from DEAE-cellulose between 0.1 M and 0.25 M KCl, and was concentrated by precipitation with ammonium sulphate.

Extracts prepared from PHA-stimulated lymphocytes incorporated considerably more 14 C-leucine into protein than those from unstimulated cells. In both cases at least 90% of the incorporation was due to the completion of polypeptide chains initiated in the intact cell, as judged by its insensitivity to inhibitors of initiation such as aurin tricarboxylic acid and pactamycin. These results were very similar to those obtained previously with ribosomes from stimulated and unstimulated human lymphocytes⁸.

35 S-methionyl-tRNA Met added to such extracts rapidly became bound to 40S ribosomal subunits, either at 0° C or at 37° C, but there was always more binding to the subunits in the extracts from stimulated cells (Fig. 1). This difference was not due to differential hydrolysis of the 35 S-methionyl-tRNA, as only about 5% was hydrolysed during the incubation period, and the rate of hydrolysis with either extract was not much faster than that with buffer alone.

Little 35 S-methionyl-tRNA became bound to 80S ribosomes in extracts from unstimulated lymphocytes, while there was significant but rather variable radioactivity sedimenting in both the 80S and the polyribosome regions of extracts from PHA-stimulated cells. In some extracts more

methionyl-tRNA was bound to the 80S and polyribosome regions than in the 40S region. The sedimentation of radioactivity in the 80S region was abolished by 10^{-4} M aurin tricarboxylic acid, but not by 3×10^{-3} M cycloheximide.

Addition of globin mRNA increased the binding of 35 S-methionyl-tRNA to the 80S region, but had little effect on the difference between stimulated and unstimulated cell extracts (Fig. 1). The extracts from the PHA-stimulated cells were thus able to utilise the added mRNA more effectively. The amount of radioactivity sedimenting in the 40S region was not much altered by the addition of mRNA, although the peak of radioactivity did sediment a little further down the gradient.

In contrast, the binding of 35 S-methionyl-tRNA to both 40S and 80S regions was greatly increased, and the difference between stimulated and unstimulated extracts almost completely overcome, by the addition of initiation factors from reticulocyte ribosomes (Fig. 2). The binding to the 80S region was abolished by 10^{-4} M aurin tricarboxylic acid or 10^{-5} M edeine. Both these inhibitors prevent the formation of normal mRNA-containing 80S initiation complexes^{9,10}, but do not inhibit the non-specific binding of tRNA to 80S ribosomes, such as occurs at high Mg^{2+} concentrations¹¹. The reticulocyte initiation factor preparation did not contain significant amounts of mRNA, as judged by its inability to cause a 'shift' reaction in sparsomycin-treated reticulocyte lysates¹², so that the mRNA required for the binding of the methionyl-tRNA to the 80S ribosome must be derived from the lymphocyte extracts. Addition of globin mRNA to either type of extract in the presence of reticulocyte initiation factors markedly increases the binding to the 80S region (Fig. 1). In this case the amount of methionyl-tRNA bound to the 40S region, and the amount at the top of the gradient are both reduced, and the slight shift in the sedimentation rate of the radioactivity in the 40S region is more pronounced.

In a previous series of experiments⁸ we showed that after stimulation by PHA, lymphocyte ribosomes contained a higher concentration of those initiation factors required for the translation of the synthetic mRNA poly(U) at low Mg^{2+} concentrations. The results presented here support much more directly the idea that the low rate of initiation in unstimulated lymphocytes is not due simply to a lack of available mRNA, but is due to a lack of one or more of the initiation factors that can be extracted from reticulocyte ribosomes.

Rosette formation of human erythrocytes on cultured cells of tumour origin and activation of complement by cell membrane

WHEN some cultured cells (OAT cells¹, a cultured cell line from lung cancer) were treated with normal fresh human, guinea pig or rabbit serum and mixed with human erythrocytes (HuE), rosette formation of HuE occurred around the treated cells. We thought initially that the phenomenon might involve natural antibodies and complement because antigen-antibody-complement complexes are known to adhere to HuE by the phenomenon of immune adherence². This possibility was excluded by the finding that rosette formation of HuE around serum-treated cultured cells occurred in the absence of Ca^{2+} , since Ca^{2+} is known to be essential for the reaction of the first component of complement (C1). That the alternative pathway of complement activation³ (Properdin system) might underlie the generation of rosette-forming ability was suggested by the demonstration that Mg^{2+} was an essential requirement.

In the following experiments, gelatin-veronal-buffered saline (GVB) containing 0.1% gelatin was used as the diluent. Three modified diluents were prepared to characterise the role of Ca^{2+} and Mg^{2+} : (1) Ca^{2+} - Mg^{2+} -GVB containing 0.15 mM CaCl_2 and 0.5 mM MgCl_2 ; (2) Mg^{2+} -EGTA-GVB containing 10.5 mM MgCl_2 and 10 mM EGTA (ethyleneglycoltetraacetate); (3) EDTA-GVB containing 10 mM EDTA (ethylenediaminetetraacetate).

OAT cells were treated with diluted serum in Ca^{2+} - Mg^{2+} -GVB, Mg^{2+} -EGTA-GVB or EDTA-GVB (Table 1). After treatment with serum at 30° C for 30 min, cells were washed three times with EDTA-GVB and mixed with HuE. After 1 h incubation at 30° C, the cells were examined microscopically, and the percentage of rosette-forming cells were calculated. Cells which bound two or more HuE were regarded as positive.

In the absence of divalent cations (in EDTA-GVB), OAT cells did not form rosettes with HuE. In the presence of Mg^{2+} , OAT cells developed the rosette-forming ability even in the absence of Ca^{2+} (Table 1). This differential dependence on Mg^{2+} was also found where guinea pig and rabbit serum were used instead of human serum.

Cultured cells derived from Burkitt's lymphoma (Daudi⁴ and P3HR-1 (ref. 5)), HeLa cells and Chang Liver cells were treated with human serum (at a final concentration of 1:15) in the presence or absence of Ca^{2+} and/or Mg^{2+} as described above.

Daudi cells and P3HR-1 cells were able to form rosettes with HuE following treatment with Mg^{2+} -EGTA-GVB but HeLa cells and Chang Liver cells were not (Table 2). In a similar experiment, four cell lines derived from biopsies of nasopharyngeal carcinoma (NPC204, NPC316, NPC415 and NPC428)⁶ all acquired the ability to form rosettes after treatment with human serum in Mg^{2+} -EGTA-GVB. Two primary cultures of acute myeloid leukaemia cells were unable to form rosettes.

OAT cells were also treated with C4-deficient guinea pig serum⁷ in the presence or absence of divalent cations. After treatment in the presence of Mg^{2+} , OAT cells were found to form rosettes of HuE and also to fix C3 molecules on the cell membrane. C3 was detected by use of ¹²⁵I-labelled (Fab')₂ antibody to guinea pig C3. OAT cells treated with

TABLE 1 Rosette formation of HuE around OAT cells treated with human serum in the presence or absence of Ca^{2+} and/or Mg^{2+}

Diluent	Dilution of human serum*			
	1:20	1:60	1:200	0
Ca^{2+} - Mg^{2+} -GVB	56†	48	5	0
Mg^{2+} -EGTA-GVB	43	20	0	1
EDTA-GVB	1	2	0	0

To 0.2 ml 5×10^5 ml⁻¹ OAT in GVB was added 0.1 ml of Ca^{2+} - Mg^{2+} -GVB, Mg^{2+} -EGTA-GVB or EDTA-GVB. To each of these, 0.1 ml of a dilution of human serum in corresponding buffer (Ca^{2+} - Mg^{2+} -GVB, Mg^{2+} -EGTA-GVB or EDTA-GVB) was added. After 30 min incubation at 30° C, the treated OAT cells were washed and resuspended in 0.05 ml of EDTA-GVB and mixed with 0.05 ml of 4×10^7 ml⁻¹ HuE in EDTA-GVB. After 1 h at 30° C, rosette formation of HuE around the treated OAT cells was observed microscopically.

* Final concentration in the above reaction mixture.

† Percentage of OAT cells binding two or more HuE.

C4-deficient guinea pig serum in EDTA-GVB did not form rosettes and did not fix C3. These findings indicated that the cell membrane of cells such as OAT, Daudi, P3HR-1 and NPCs had the ability to activate C3 molecules and to cause them to associate with the cell membrane. It has been reported that trypsinisation of HuE results in loss of the immune adherence receptor⁸. Since trypsinised HuE did not form rosettes on serum-treated OAT cells, a likely interpretation is that the interaction of cell membrane immune adherence receptors and membrane bound C3 is involved in the mechanism of rosette formation. Activation of C3 probably occurs through the alternative pathway³, since the reaction occurred with C4-deficient serum and required Mg^{2+} . An antigen-antibody reaction is unlikely to be involved since sheep erythrocytes sensitised with antiserum did not form rosettes with HuE even after the treatment with human serum in Mg^{2+} -EGTA-GVB. If it is postulated that the process of rosette formation is based on complement activation by the alternative pathway³, the cell membrane of rosette-forming cells may have some molecular configuration similar to that of bacterial lipopolysaccharides which also have the ability to activate the alternative pathway of complement.

To examine the relationship between the rosette-forming ability and virus infection, the following experiment was performed with acute myeloid leukaemia cells. The cells were found to lack rosette-forming ability following treatment with serum in Mg^{2+} -EGTA-GVB. Suspensions of cells were added to spleen extracts of DDD mice suffering from Friend leukaemia, to tissue culture fluid of C3H2K cells infected with Moloney sarcoma virus and to a spleen extract of DDD mice infected with Rauscher virus. Cells were incubated in RPMI 1640 medium containing 20% heat-inactivated α - γ human serum at 37° C under 5% CO_2 . After 12, 36, 60, 84 and 108 h incubation, cells were tested for rosette-forming ability.

TABLE 2 Percentage of rosette-forming cells after treatment with 1:15 human serum in presence or absence of Ca^{2+} and/or Mg^{2+}

Cells	1:15 dilution* of human serum in		
	Ca^{2+} - Mg^{2+} -GVB	Mg^{2+} -EGTA-GVB	EDTA-GVB
Daudi	62%†	49%	0%
P3HR-1	36%	36%	3%
HeLa	7%	0%	0%
Chang liver	11%	1%	0%

To 0.2 ml of 5×10^5 ml⁻¹ cells in GVB was added 0.2 ml of the appropriate diluent; then they were mixed with 0.2 ml of 1:5 dilution of human serum in the corresponding diluent (Ca^{2+} - Mg^{2+} -GVB, Mg^{2+} -EGTA-GVB or EDTA-GVB). After 30 min incubation at 30° C, the treated cells were washed and reacted with HuE as in the legend of Table 1.

* Final concentration in the reaction mixture.

† Percentage of cells binding two or more HuE.

TABLE 3 Effect of addition of virus-rich materials on rosette-forming ability of acute myeloid leukaemia cells

Materials added	Rosette forming ability* after an incubation period of (h)				
	12	36	60	84	108
Friend virus (Spleen extract)	3	0	4	2	3
Moloney sarcoma virus (Tissue culture fluid)	1	0	2	3	25
Rauscher virus (Spleen extract)	0	1	0	2	3
None	0	0	0	1	1

From heparinised blood of an acute myeloid leukaemia patient, a leukaemic cell fraction was collected and suspended in RPMI 1640 medium with 20% heat-inactivated α - γ human serum† at a concentration of 1.5×10^6 ml⁻¹. To 9 ml of the cell suspension, 0.3 ml of Friend virus fraction (spleen extract), 0.6 ml of Moloney sarcoma virus fraction (tissue culture fluid) or 0.3 ml of Rauscher virus fraction (spleen extract) were added. To the control cell suspension nothing was added. Each mixture was separated into 6 tubes each of which contained 1.5 ml. They were incubated at 37 °C under 5% CO₂. After incubation, cells of each tube were washed three times with GVB and resuspended in 0.4 ml of Mg²⁺-EGTA-GVB. To the cell suspension, 0.2 ml of 1:3 dilution of human serum in Mg²⁺-EGTA-GVB were added and the mixture was incubated at 30 °C for 30 min. After washing with EDTA-GVB three times, cells were resuspended in 0.2 ml of GVB and mixed with 0.2 ml of 2×10^6 ml⁻¹ HuE in EDTA-GVB. Rosette formation of HuE on the cells were observed after 1 h at 30 °C.

* Percentage of cells binding two or more HuE.

† From normal human serum of Type O, γ -globulin fraction was removed by 45% saturation of ammonium sulphate. The α - γ human serum was dialysed against saline to remove ammonium sulphate and then dialysed against foetal calf serum to reconstitute dialysable serum factors before use.

following treatment with human serum in Mg²⁺-EGTA-GVB. Cells which had been mixed with material rich in Moloney sarcoma virus became able to form rosettes after 108 h incubation (Table 3). This finding suggested that rosette-forming ability could be brought about by viral infection. If cells able to activate complement non-specifically are either present or are generated *in vivo*, phenomena simulating immunological reactions may occur without reactions of specific antigens and antibodies. Such a mechanism may be involved in the pathogenesis of changes occurring in some of the so-called autoimmune diseases.

We thank Dr M. M. Frank for his kind gift of C4-deficient guinea pig serum, Dr T. Odaka for fractions of Friend leukaemia, Moloney sarcoma and Rauscher leukemia viruses, Dr S. Oboshi for OAT cells and Dr M. Takada for NPC cells.

Temperature dependence of cation permeability of dog red cells

It has been suggested that changes in the physical state of phospholipids are responsible for the observed dependence upon temperature and membrane composition of the self-diffusion of sodium ions through lipid vesicles¹ and of diverse membrane transport processes²⁻⁴ some of which are mediated by enzymes^{5,6}. This is supported to some extent by the detection of phase-transitions in both natural membranes⁷⁻¹⁰ and in lipid-extracts¹¹⁻¹³ using X-ray diffraction and other techniques. It seems, however, that only membranes of low cholesterol content exhibit any of the usual characteristics of these transitions^{1,9,12,13}.

We report here that the transport of sodium ions into dog red cells, under isotonic conditions, increases as the temperature is lowered from 38° C and reaches a maximum at 22–25° C. By contrast, the influx of potassium ions is described by a normal Arrhenius relationship between 38° C and about 12° C at which temperature a well-defined minimum is reached. This implies that the fluidity of the lipids in the membranes of these cells, which are rich in cholesterol, does influence the fluxes of sodium and potassium. Furthermore, the disparity between the effects of temperature on the fluxes, which are mainly passive in this system, indicates that two independent processes are involved in the ion-transport mechanisms.

Blood was drawn from the jugular vein of unanaesthetised Beagles into syringes wetted with heparin. Within a few minutes it was chilled to 4° C and centrifuged at about 1900g (MSE Minor). Plasma and white cells were aspirated and the red cells were washed three times at 4° C with a solution containing NaCl 142.2 mM, KCl 5.0 mM, Na₂HPO₄ 5.2 mM, NaH₂PO₄ 0.8 mM, CaCl₂ 1.0 mM, MgCl₂ 0.25 mM, glucose 5.0 mM and 1% (w/v) bovine serum albumin (Sigma, fraction V). The washed cells were suspended (5 ml packed cells to 25 ml of bathing medium) in Erlenmeyer flasks which were placed on ice. ¹³¹I-human serum albumin (Radiochemical Centre, Amersham) was passed through an ion exchange resin (Deacidite FF-1P, Permutit) before it was made up in isotonic buffer and added to each suspension (2 μ Ci ml⁻¹).

Cell suspensions were shaken in a water bath at 38° C for 30 min and then transferred to shaking water-baths at the temperature of the influx of ²⁴Na and left for a further 30–45 min at 38° C, or for 1–2 h at lower temperatures. At the end of these incubation periods, 0.2–1.0 ml of buffer solutions containing either ²⁴Na or ⁴²K (Radiochemical Centre, Amersham) were added to each suspension (10 μ Ci ml⁻¹) at 15 s intervals after which the suspensions were agitated vigorously for 2 min. At various times thereafter, 4 ml samples of each suspension were pipetted into centrifuge tubes pre-cooled in ice-water. These were transferred to the cold room (4° C) and centrifuged for 3–5 min. Samples of the supernatants were saved and the remainder aspirated. 100 μ l volumes of the packed cells were taken using a gas-tight Hamilton syringe with a Chaney adaptor (Reno, Nevada) and lysed by addition to 2 ml of water in Pyrex test-tubes. The Hamilton syringe was calibrated and served as the primary reference for the volume of packed cells in each lysate; it was rinsed several times with detergent solution (2% Triton X-100) and water between each pipetting. At temperatures between 20° C and 38° C, samples of red cell suspensions were taken at 30–60 min intervals throughout 3–5 h, but below 20° C samples were taken at less frequent intervals spaced over 12–15 h. The radioactive supernatants were diluted and prepared for γ -counting in the same way as the lysates. The activities of ²⁴Na (or ⁴²K) and ¹³¹I were measured in a two-channel γ -counter (Packard, Model 3002 or LKB Wallac 80000) and the appropriate corrections for

Fig. 1 Arrhenius plots of steady-state fluxes of sodium and potassium in dog red cells. The values of the fluxes (meq per l cells h^{-1}) at $38^{\circ}C$ were 2.28 ± 0.35 (+), 3.96 ± 0.10 (Δ) and 2.87 ± 0.25 (O) for sodium, 0.0645 ± 0.0012 (\bullet) and 0.0703 ± 0.0049 (\blacksquare) for potassium. Blood from a different animal was used in each set of flux measurements. The errors arise mainly from the standard errors of the regression lines fitted by the method of least squares to 3–5 points on an uptake curve. In one experiment (O—O) the cells were not pre-incubated at $38^{\circ}C$ as described in the text, but were left in ice for a few hours after washing, and then gently agitated for 1–2.5 h at the temperature of ^{24}Na -uptake before the addition of tracer. The least squares fit to the ascending limb of (+—+) gave a negative apparent activation energy for sodium influx of 8.7 ± 0.3 kcalorie mol^{-1} and for the descending limb a positive value of 28.2 ± 0.6 kcalorie mol^{-1} , one point at $22.4^{\circ}C$ appeared to be common to both limbs of the Arrhenius plot. The activation energies for potassium influx between $38^{\circ}C$ and $15^{\circ}C$ were 8.5 ± 0.3 kcalorie mol^{-1} (\blacksquare — \blacksquare) and 9.2 ± 1.2 kcalorie mol^{-1} (\bullet — \bullet); below the 'transition' temperature at 11 – $13^{\circ}C$ the value was about -22 kcalorie mol^{-1} .

^{24}Na (or ^{42}K) activity in the ^{131}I channel were made. Finally the concentrations of haemoglobin, sodium and potassium in each lysate were measured. After correcting for tracer in the trapped extracellular volume of the packed cells, it was possible to calculate the ^{24}Na or ^{42}K uptake in terms of activity per unit cell volume, the relative volume of the cells from the intracellular concentration of haemoglobin, and the intracellular concentrations of the cations from which net movements of Na and K could be estimated to check if the cells were in the steady-state. This method for the measurement of tracer uptake in cell suspensions has obvious advantages over the more conventional techniques which involve repeated washing of the cells in cold isosmolar $MgCl_2$ (ref. 14) or $NaSCN$ (ref. 15) solutions to remove 'extracellular' tracer.

Provided that extracellular tracer had exchanged with less than 20% of the intracellular cation, the uptake of ^{24}Na or ^{42}K was usually linear with time except for a small deviation

at times less than about 20 min. This initial curvature probably represents the penetration of tracer into a small space (less than about 1.5%) beyond that accessible to ^{131}I -albumin yet still extracellular. Fluxes (meq per l cells h^{-1}) of sodium and potassium were calculated from the ratio of the slope of the regression line fitted to the uptake of the tracer and the extracellular specific activity of the cation.

The temperature dependence of the cation fluxes is illustrated by the Arrhenius plots in Fig. 1. It was surprising to find that the sodium flux was maximal at about $22^{\circ}C$ at which temperature the flux was three times greater than at $38^{\circ}C$. By contrast, the potassium flux decreased as the temperature was lowered from $38^{\circ}C$ to about $12^{\circ}C$, and then passed through a minimum. At all temperatures the cells remained at constant volume throughout the uptake of the tracers as indicated by the measurements of intracellular haemoglobin. Within experimental error the intracellular cation contents did not vary significantly with temperature, although cell volume at 18 – $22^{\circ}C$ was slightly ($\leq 3.7\%$) greater than at $38^{\circ}C$. This difference in cell volume, however, could not account for the results as it is established that as dog red cells swell sodium flux decreases and potassium flux increases^{16–18}.

Vieira *et al.*¹⁹ have shown that the apparent activation energies for both the hydraulic conductivity and the diffusion permeability of water in dog red cells are constant from $37^{\circ}C$ to $7^{\circ}C$. Taken in conjunction with the present results, this implies that the translocation of water, potassium and sodium across the membrane of this type of cell takes place by means of independent mechanisms and that the transport of either cation cannot occur through water-filled pores in the membrane. Furthermore, the lack of coupling between the effects of temperature on the transport of the different species makes it unlikely that any long-range reorganisation of the membrane lipids occurs when the fluxes of sodium and potassium are maximal and minimal respectively. It seems more likely that changes in the conformation of localised lipid-protein complexes are involved.

Davson and Reiner²⁰ first showed that the net efflux of sodium from cat red cells suspended in KCl solutions was maximal at around physiological temperatures and, more recently, this has been confirmed in cells under steady-state conditions²¹. Therefore, while cat and dog cells have a number of characteristics in common in that they are sodium-rich, have a low Na-K ATPase activity²² and have a cation transport system that is dependent on cell volume^{16–21,23}, it would seem that there is a marked shift in the temperature at which the permeability of the membranes to sodium is maximum. It may be possible to relate this to the small but definite differences in the lipid composition of the membranes²⁴.

It is worth noting perhaps that a 'suggestion' of a phase-transition at about $22^{\circ}C$ in human red cell ghosts has been found recently using a dilatometric technique²⁵.

We thank Colin Green at the Clinical Research Centre for providing the dog blood.

Deficiency of two enzymes of galactose metabolism in kangaroos

THE starting point of the investigation reported here was the observation by one of us of diarrhoea and occasional cataract formation in bottle-fed orphan pouch-young kangaroos. As kangaroo milk has a very low lactose content¹⁻³ and the intestinal lactase content of pouch-young kangaroo is also low⁴, we thought that these marsupials may not utilise galactose, present mainly as polygalactan in milk, by the usual pathway involving galactokinase (E.C. 2.7.1.6) and galactose-1-phosphate uridyl transferase (E.C. 2.7.7.12) (transferase). With this postulate, and the role of deficiency of these two enzymes in human cataractogenesis in mind, galactokinase and transferase were assayed in haemolysates from the grey (*Macropus giganteus*) and the red kangaroo (*Megaleia rufa*).

Blood was collected from lateral tail veins of unanaesthetised adult male and female kangaroos, and by venepuncture from normal adult humans of both sexes. Haemolysates were pre-

TABLE 1 Erythrocytic galactokinase and galactose-1-phosphate uridyl transferase of grey and red kangaroos

Species	Galactokinase ($\mu\text{mol galactose}$ phosphorylated $\text{h}^{-1} \text{ml}^{-1}$ RBC)		Galactose-1-phosphate uridyl transferase (U g^{-1} haemoglobin)	
	No.	Mean \pm s.d.	No.	Mean \pm s.d.
Grey kangaroo	22	0.039 ± 0.013	19	2.2 ± 1.7
Red kangaroo	21	0.033 ± 0.009	20	10.6 ± 3.5
Human	200	0.213 ± 0.028 (7)	61	21.4 ± 3.2

Statistically, galactokinase and transferase values from both species of kangaroos were significantly different ($P < 0.001$ in all comparisons) from human values. Galactokinase was not significantly different between two species of kangaroos, but transferase was so ($P < 0.001$). RBC, red blood cells.

TABLE 2 Amount of methaemoglobin reduced in 3 h with either galactose or glucose as substrate by erythrocytes from grey and red kangaroos

Species	No.	% Methaemoglobin reduced	
		Galactose substrate	Glucose substrate
Red kangaroo	6	5.0 ± 1.8	15.2 ± 5.3
Grey kangaroo	6	1.9 ± 1.4	11.4 ± 3.6
* Human	14	10.2 ± 2.0	28.0 ± 5.2

* Human values as reported earlier⁵.

pared and galactokinase was assayed as previously described⁵. Transferase was determined using Sigma Kit (Sigma), by the UDPG consumption test⁶, as described in *Sigma Technical Bulletin* No. 600-UV. A normal blood sample was always used as control for each batch of assays for both enzymes. To study the overall utilisation of galactose by erythrocytes, a modified methaemoglobin reduction test was performed for 3 h as described earlier⁵, with galactose as substrate; glucose was used as substrate for comparison.

The results of enzyme assay are shown in Table 1. In both red and grey kangaroos, galactokinase activity was about one-sixth of the normal human value. It should be noted that red cell galactokinase activity in both species was much lower than in various other mammals⁵. A distinct difference between the two species was observed with regard to transferase, in that the grey kangaroo almost completely lacked this enzyme, whereas the red kangaroos had levels approximating those in humans heterozygous for galactose-1-phosphate uridyl transferase deficiency. Erythrocytic haemolysates from seven of the nineteen grey kangaroos had enzyme activity of less than 1U, and four of these had no activity at all. In both species, similar values of galactokinase and galactose-1-phosphate uridyl transferase were found in males and females.

The combined effect of the deficiency of both galactokinase and transferase in grey kangaroos and of galactokinase, but not transferase, in red kangaroos is suitably demonstrated by measuring rates of methaemoglobin reduction with galactose as substrate (Table 2). While both grey and red kangaroos were substantially less able to reduce methaemoglobin than humans, this deficiency was more pronounced in grey than in red kangaroos. The faster rates of methaemoglobin reduction with glucose as substrate indicate that the galactose pathway limits the rate of methaemoglobin reduction in both kangaroos and humans.

We are presenting these results to draw attention to the possibility that other marsupials may prove to be deficient in enzymes of galactose metabolism, and that such animals may provide useful models for galactose cataractogenesis. Mathai *et al.*⁷ investigated the possibility of using California sea lions (*Zalophus californianus*), whose milk is completely deficient in lactose, for the study of the pathogenesis of galactosaemia in man, but found that their erythrocytes were not deficient in either galactokinase or transferase activity, possibly due to the high galactose content of mucopolysaccharides in various aquatic organisms on which they feed. In view of their almost complete lack of transferase, grey kangaroos may be a very useful animal model for the study of galactosaemia in man.

Mammatropic effect of prolactin enhanced by thyroidectomy

THE role of thyroid hormones in relation to mammary gland structure and function has received sporadic attention. It has been shown in the rat that thyroid hormones are not necessary for mammary development¹ and that in ovariectomised, adrenalectomised, hypophysectomised rats, prolactin and growth hormone are the principal hormones responsible for lobulo-alveolar growth². The slight stimulatory effect of thyroid hormones on mammary growth and lactation in animals has been attributed to their general metabolic effects^{3,4}. There are, however, a few contrary reports in the literature describing greater mammary development in rats rendered hypothyroid^{5,6}, which have remained unexplained. The present study was undertaken to clarify the relationship between thyroid hormones and mammary growth, with special reference to prolactin. Interest in this field was primarily aroused by several clinical and epidemiological reports associating thyroid hypofunction with breast cancer^{7,8}.

Two separate experiments were carried out. In the first, thirty-six Sprague-Dawley female rats, weighing about 200 g, were divided into six equal groups. They were fed on a commercial diet and given tap water *ad libitum*. All rats, including controls, were given oestradiol (8 µg subcutaneously s.c.) daily from day 1 of the experiment to day 10 inclusive¹⁰. In addition, rats in each group were treated as described in the legend to Fig. 1. The animals were killed on day 16. The left inguinal mammary glands were removed, fixed in buffered formal saline, processed for histology, and the sections stained with haematoxylin and eosin (Fig. 1). In oestrogen-primed rats, thyroidectomy induced a marked stimulation of mammary development, which was completely suppressed by replacement doses of thyroxine. A marked suppression of mammary stimulation also occurred when 2-bromo-α-ergocryptine (CB154), a compound known to reduce but not abolish prolactin secretion⁹, was administered. By raising the prolactin level with perphenazine¹⁰, the mammary glands of thyroidectomised rats could be still further stimulated with the production of macroscopic secretion.

In the second experiment twenty Sprague-Dawley rats, weighing about 200 g, were divided into two groups of ten and fed and watered as in the first experiment. All rats were ovariectomised and thyroidectomised on day 1 of the experiment. Each rat received daily injections of oestradiol (1 µg s.c.), progesterone (3 mg s.c.) and thyroxine (2 µg per 100 g body weight i.p.) from day 1 to day 15. One group received bovine thyrotropic hormone daily (TSH:1.5 IU (s.c.)) from day 11 to day 15, the second group remained as untreated controls. All rats were killed on day 16 and the mammary glands removed and processed as in the first experiment. Histological examination showed no difference between the two groups.

The marked enhancement of mammary development by thyroidectomy in the first experiment might be explained

by the following possibilities: (1) thyroidectomy causes an increase in the secretion of prolactin and/or growth hormone; (2) thyroidectomy causes an increased secretion of ovarian oestrogens which in turn stimulates prolactin secretion; (3) TSH, which is increased after thyroidectomy, has mammatropic properties; (4) prolactin exerts a greater mammatropic effect in the absence of thyroid hormones.

The first two possibilities are unlikely as measurement of prolactin and growth hormone levels in the blood of hypothyroid rats, by sensitive radioimmunoassay methods, has shown that there is no significant change in the prolactin level, whereas there is a dramatic fall in the level of growth hormone¹¹. Previous observations by Leonard and Reece⁶ of greater mammary development in thyroidectomised-ovariectomised rats compared to ovariectomised controls, also excludes the involvement of ovarian hormones in this phenomenon. The third possibility that TSH may have mammatropic properties is proved unlikely by the second experiment. Therefore, it seems that the fourth possibility is the most likely: that in the absence of thyroid hormones, the mammatropic effect of a normal level of endogenous prolactin is markedly increased and that further stimulation occurs when the prolactin level is raised by pharmacological means.

FIG. 1 Photomicrographs of sections of mammary gland showing the relationship between the effects of prolactin and thyroxine on mammary development in the rat. Stain: haematoxylin and eosin $\times 52$. All rats, six per group, were given oestradiol 8 µg s.c. daily from day 1 to day 10 inclusive and killed on day 16. In addition, rats in each group were treated as indicated: a, Control group (no additional treatment) showing clusters of ducts amidst mammary fat with little alveolar formation. b, Thyroidectomy (on day 1), marked duct and alveolar development replacing mammary fat. Alveoli contain secretion. c, Thyroidectomy (on day 1) + thyroxine (in alkaline solution) 2 µg per 100 g body weight per day i.p. from day 1 to day 15 mammary development comparable with the control group. d, Thyroidectomy (on day 1) + 2-bromo-α-ergocryptine (in 70% ethanol) 400 µg per 100 g body weight per day i.p. from day 1 to day 15. Reduction in the quantity of developed glandular tissue compared with b occupying a lesser volume of mammary fat. e, Perphenazine 5 mg per kg body weight per day s.c. from day 11 to day 15. Marked glandular development with alveolar secretion. f, Thyroidectomy (on day 1) + perphenazine 5 mg per kg body weight s.c. from day 11 to day 15. Extreme mammary development, alveoli distended with secretion. Total replacement of mammary fat.

If one assumes that the converse holds true, that excess thyroxine inhibits the mammatropic action of prolactin, then the phenomenon reported by Meites and Kragt¹² might be explained in the light of my findings. These workers observed prolactin induced mammary development around an ectopically transplanted pituitary in immature hypophysectomised rats, which was unexpectedly abolished when thyroxine was administered, despite an increase in weight of the animals. Although thyroid hormones are galactopoietic in physiological doses¹³, suppression of lactation is known to occur in the rat¹⁴ and mink¹⁵ when pharmacological levels of thyroactive substances are administered; large amounts of thyroid hormones being required presumably to block the elevated prolactin level during lactation.

A prolactin-thyroxine antagonism is also known to occur in some lower vertebrates. In urodele development, thyroxine is responsible for 'land drive' and prolactin for 'water drive', the effect of one hormone being reversed by the other under experimental conditions¹⁶. Etkin has recently drawn attention to a similar antagonism in amphibian metamorphosis¹⁷; repeated injections of prolactin in larval tadpoles prevents thyroxine-induced metamorphosis into adult structures until additional thyroxine is given¹⁸. Bern and Nicoll¹⁹ have suggested that this antagonism takes place at a peripheral tissue level. The present experiment indicates a similar antagonism at the level of the rat mammary epithelium.

If hypothyroidism sensitises the rat mammary epithelium to the action of prolactin, this condition should also enhance 7,12-dimethyl-benz(a)anthracene (DMBA)-induced mammary tumorigenesis, which is prolactin dependent²⁰. Shellabarger²¹ obtained twice as many tumours in rats rendered hypothyroid by propylthiouracil (PTU) administered for only two weeks before DMBA, compared with controls; but continuous PTU treatment, maintained after DMBA, suppressed tumour production. Therefore, hypothyroidism enhances tumour initiation but cannot promote tumour growth, presumably due to disappearance of growth hormone from blood²².

The antagonism between prolactin and thyroxine at the level of the rat mammary gland is a new finding the mechanism of which remains to be investigated. In view of a similar observation in some lower vertebrates, a wider implication of this phenomenon cannot be excluded. It is possible that the level of thyroid hormones in blood determines the 'set point' for the mammatropic effect of prolactin. Reports of massive virginal breast hypertrophy in association with hypothyroidism²³ and objective and subjective improvement after thyroid therapy in women suffering from mammary dysplasia^{23,24} point to possible clinical evidence of a similar phenomenon.

I thank Professor I. Doniach of The London Hospital and Mr. J. L. Hayward of Guy's Hospital for their encouragement and advice. I thank Dr R. C. Hallows, Miss D. Lewis and Dr R. D. Bulbrook of The Imperial Cancer Research Fund for their help.

Oestradiol inhibition of collagenase role in uterine involution

THE uterus of the rat provides an ideal organ for the study of collagen breakdown; during the *post partum* involution of this organ the half-life of the uterine collagen is reduced to 24–30 h. Previous studies have shown that this rapid breakdown of collagen in the rat uterus is accompanied by extensive phagocytosis of collagen^{1–3}, elevated lysosomal enzyme levels⁴, the presence of hydroxyproline in lysosome-like particulates, and an increase in the concentration of a collagenolytic cathepsin which digests collagen at acid pH (ref. 5). All of these findings are consistent with the intracellular ingestion and digestion of the extracellular collagen fibres.

None of these findings, however, gives a clear explanation of how the fibres are broken into fragments and brought inside the cell, nor do they allow an evaluation of the relative contributions of intra and extracellular digestion processes. It has been suggested that an extracellular collagenase active at neutral pH is required for the first step in collagen breakdown⁶. Such a collagenase has been demonstrated by culturing fragments of rat uterus; the collagenase is secreted into the culture medium from which it can be purified and characterised⁷. Enzyme is produced only by tissue from involuting uteri⁸. This method enables measurement of the potential of the tissue for collagenase elaboration but it does not reveal how much enzyme is actually present in the tissue. Recently, we have developed a method which enables the direct measurement of collagenase in the particulate fraction of uterine homogenates⁸. We have shown that the method is relatively specific for collagenase⁹ and that the enzyme being measured is a true collagenase¹⁰. Here we report findings obtained by applying this assay to the rat uterus in various stages of pregnancy and involution.

It has further been shown that oestradiol is a potent and selective inhibitor of collagen breakdown in the uterus¹¹. In searching for explanations for this effect it was shown that lysosomal enzyme levels, acid collagenolytic cathepsin activity, and collagen peptidase activity remained unaffected⁵. It has also been shown that oestradiol does not affect collagenase production by uterine slices in culture¹². We investigated whether oestradiol affected uterine collagenase when the hormone was administered to the intact rat.

TABLE 1 Collagenase activity in the involuting uteri of control and estradiol-treated rats

Experimental group	No.	Hydroxyproline (mg per uterus)	Collagen digestion (%)	Collagen digestion (μ g hydroxyproline per uterus)
Non gravid	5	1.36 \pm 0.05	2.0 \pm 1.0	27 \pm 14
Pre partum (1 d)	5	6.89 \pm 0.90	0.70 \pm 0.68*	49 \pm 48
Parturition	6	8.80 \pm 2.20	2.9 \pm 1.1	226 \pm 113
Post partum controls:				
Day 1	5	8.10 \pm 1.39	5.1 \pm 2.3	396 \pm 129
Day 2	8	4.63 \pm 0.39	14.0 \pm 2.8	658 \pm 182
Day 3	6	1.73 \pm 0.37	12.9 \pm 2.9	220 \pm 52
Day 4	7	0.89 \pm 0.35	8.2 \pm 1.8	77 \pm 36
Oestradiol-treated:				
Day 1	5	8.08 \pm 1.32	4.7 \pm 1.4	368 \pm 84
Day 2	8	4.88 \pm 0.49	4.6 \pm 0.9†	237 \pm 120†
Day 3	6	3.94 \pm 0.34†	5.3 \pm 0.8†	207 \pm 30
Day 4	5	3.80 \pm 0.89†	2.1 \pm 1.0†	73 \pm 20

All values given as mean \pm s.d.

* This value differs from parturition by $P < 0.01$ and from non-gravid by $P < 0.05$.

† Value significantly ($P < 0.001$) less than relevant control.

Pregnant female rats were purchased from Sprague-Dawley Farms, Madison, Wisconsin, at the 17th day of gestation and were maintained on Purina rat chow. The time of delivery was recorded and the young were allowed to nurse. Injections of 17β -estradiol (Mann Research Laboratories, New York) were administered intraperitoneally as a suspension of the hormone in 0.9% NaCl (100 μ g in 0.1 ml.) shortly after delivery was complete and on each successive day. Uteri were removed and dissected free of mesentery and placental sites. Preparation of tissue homogenates and determination of collagenase activity in the 6000g pellets were as previously described⁸. The collagen of the uterus served as the substrate for the collagenase, and EDTA blanks were used in every case.

The major findings are presented in Table 1. The % collagen digestion was measured in the 6000g pellet from 0.2 g wet uterine tissue in a total volume of 2.0 ml. All of the pellets at all points contained approximately the same amount of collagen (about 700 μ g hydroxyproline) with the exception of the 3 and 4 d controls (about 500 μ g). Therefore, as substrate and tissue weight were constant, the results are essentially a measure of enzyme concentration. The total digestion per uterus (final column) was calculated by multiplying the % digestion by the total hydroxyproline content for each sample. This provides an estimate of the total units of enzyme per whole organ.

Very little collagenase activity can be found in non-gravid uteri and in uteri 1 d before parturition. Collagenase rises by the time of parturition and then rapidly increases to a peak of concentration at day 2-3 and of total units at day 2 post partum. By 4 d, involution is almost complete; there is enough enzyme to digest 8% of the collagen, but the uterus contains very little remaining collagen. These data on collagenase activity correlate closely with previous studies on the rate of collagen breakdown in the involuting uterus¹¹. The maximum rate of hydroxyproline loss occurs between day 1 and 3 (Table 1). The data also agree with the finding of Jeffrey *et al.*⁶ that maximum production of collagenase in cultures of uterine tissue is observed with tissue removed at 1-2 d post partum. The correlation of activity with rate of collagen loss is not perfect, because at parturition there is an appreciable level of collagenase activity but almost no collagen degradation for the first 24 h. It should also be noted that the digestion of collagen during the 20 h assay is only about one-fifth that which occurs *in vivo* during the same period (such as day 2). The system *in vitro*, however, has been diluted 10-fold and optimum conditions may not obtain. On the other hand, other pathways for collagen breakdown may also be operative *in vivo*.

Oestradiol treatment strongly inhibits collagen breakdown. The values of hydroxyproline per uterus show that the main inhibitory effect occurs between day 2 and 3 (Table 1). It is just at the beginning of this period that the collagenase levels of oestradiol-treated animals vary most markedly from controls. At day 2 the oestradiol-treated tissue has only about one-third the control value of collagenase, whether expressed as concentration or as total units per uterus. The collagenase content never increases over that found at day 1; the concentration continues to remain low through day 4. Whereas the total activity per uterus approaches control values on days 3 and 4, the low enzyme concentration and the high collagen content prevent the treated uteri from maintaining a normal rate of collagen breakdown.

Oestradiol does not act by altering the collagen substrate: solubility and susceptibility to added uterine collagenase, acid collagenolytic cathepsin, and trypsin are unaffected. Uterine homogenates contain inhibitors which are normally discarded with the supernatant before the assay. Figure 1 shows that the supernatants from oestrogen-treated rats are, if anything, even less inhibitory than the control supernatants. Moreover, a study of the supernatants by the method of Sakamoto *et al.*¹² indicates that very little collagenase is present. All evidence

FIG. 1 Effect of 6000g supernatants of uterine homogenates on collagenase activity in uterine pellets. The preparation of supernatants and pellets and the enzyme assays are as previously described⁸. The supernatants were adjusted to pH 7.6 and added to control pellets to produce the final concentration shown. ○, Supernatant from 2 d post partum uterus of control rat; ●, supernatant from corresponding uterus of oestradiol-treated rat. A digestion of 100% of the control value corresponds to 15.2% digestion of the collagen.

to date points to the presence of fewer active molecules of collagenase in the oestrogen-treated uteri.

A recent report by Jeffrey *et al.*¹² showed that progesterone added to cultures of rat uterine tissue inhibits collagenase production, whereas oestradiol has no effect. This suggests that the oestradiol effects observed in the intact rat may not be directly mediated by the uterus.

It has been shown by Yoshinaga *et al.*¹⁴ that the rat ovaries at the time of parturition produce almost 1 µg of oestrogen per day. We showed earlier¹¹ that 1 µg of oestradiol per day clearly inhibited collagen breakdown so that by 4 d the treated uteri contained twice as much collagen as the controls. The present dose of 100 µg was selected to maximise this effect, leaving four times as much collagen at 4 d.

This research was supported by a US Public Health Service grant from the National Institute of Child Health and Human Development. J.N.R. received fellowship support from the US Public Health Service. We thank Carolyn Taplin for her excellent technical assistance. A preliminary report of this material was originally presented at the Federation meetings¹⁵.

Enhancement of cerebral noradrenaline turnover by thyrotropin-releasing hormone

THYROTROPIN-RELEASING hormone (TRH) (pyroglutamyl-histidyl-proline-amide) has been reported to ameliorate mental depression^{1,2}. The mechanism of action of the tripeptide in this condition is unknown. It may be connected with changes in the activity of noradrenergic or 5-hydroxytryptaminergic neurons which are thought to be involved in depressive states^{3,4}. Therefore, we have investigated the action of TRH on the turnover of biogenic amines in rat brain.

Male albino rats of 200 g, Wistar origin, were injected intraperitoneally with TRH. Thereafter noradrenaline, dopamine, 5-hydroxytryptamine (5-HT) as well as their corresponding main metabolites 3-methoxy-4-hydroxyphenylethyleneglycol (MOPEG, isolated as the sulphate ester),

FIG. 1 Effect of intraperitoneal injection of 10 mg kg⁻¹ TRH on the content of 3-methoxy-4-hydroxyphenylethyleneglycol (MOPEG) in the cerebral cortex of rats. Each value is expressed in percent of untreated controls (95.7 ± 2.9 ng g⁻¹ = 100%) and represents the average with s.e.m. of results from twenty to forty determinations per group performed in four to eight experiments. Each determination was carried out in two pooled cerebral cortices. Significance against controls: MOPEG concentration 0.5, 1, 2 and 4 h after TRH injection. $P < 0.001$ (Student's *t* test).

homovanillic acid and 5-hydroxyindoleacetic acid were measured in whole brain and/or various brain parts⁵ by spectrophotofluorimetric methods⁶⁻¹⁰. In other experiments the action of triiodothyronine (T₃) on the levels of MOPEG in different brain regions was determined. In animals thyroidectomised 2 d before TRH injection, estimations of MOPEG were carried out in the same cerebral regions. In addition, the effect of TRH on the accumulation of ¹⁴C-noradrenaline and ¹⁴C-dopamine in the whole brain was measured in rats injected with L-3-¹⁴C-tyrosine (30 µg in 20 µl saline; specific activity 53.9 mCi mmol⁻¹) through a permanent cannula implanted in one lateral cerebral ventricle¹¹. Labelled noradrenaline and dopamine were isolated by adsorption on alumina, separated by column chromatography on Dowex 50 × 8 and estimated in a liquid scintillation counter^{12,13}. Normal and thyroidectomised rats not injected with TRH served as controls. In the thyroidectomised animals the concentration of total thyroxine in the blood serum (measured by competitive protein-binding analysis¹⁴) had dropped to about one-fifth of its normal value and did not rise following TRH injection.

Two hours after administration of 10 mg kg⁻¹ TRH to normal rats, the cerebral content of noradrenaline, dopamine, 5-HT, homovanillic acid and 5-hydroxyindoleacetic acid did not significantly differ ($P > 0.05$) from that in untreated controls (% values after TRH: 101.0 ± 1.5%, 99.3 ± 2.9%, 102.0 ± 2.5%, 104.0 ± 3.2% and 98.7 ± 3.2%, respectively; controls: 100%). The concentration of MOPEG was, however, significantly increased ($P < 0.01$) in the whole brain as well as in the various brain regions (Table 1). In the cerebral cortex the action of TRH lasted for at least 4 h, maximal values of MOPEG (about 120% of controls) being reached between 30 min and 1 h after injection (Fig. 1). The concentration of MOPEG in various brain parts of thyroidectomised rats did not differ from that seen in controls with the exception of mesencephalon plus medulla oblongata where MOPEG concentrations were significantly increased after thyroidectomy. This elevation could not be explained. Injection of TRH, however, caused a rise of MOPEG concentration in all brain regions of thyroidectomised rats similar to that occur-

TABLE 1 Effect of TRH and T_3 , injected intraperitoneally, on the content of 3-methoxy-4-hydroxyphenylethyleneglycol (MOPEG) of whole brain and (or) various parts of rat brain

	Controls	Normal With TRH	Controls	With T_3	Thyroidectomised Controls	With TRH
Whole brain	121.3 \pm 6.0	156.1 \pm 9.0				
Cortex	105.2 \pm 3.1	126.4 \pm 4.2	93.5 \pm 2.2	103.1 \pm 2.5	98.3 \pm 2.5	120.8 \pm 2.7

Measurements were carried out 2 h after i.p. administration of 10 mg kg⁻¹ TRH or 20 μ g kg⁻¹ T_3 , respectively. Thyroidectomy was performed 2 d before injection of TRH. The figures indicate ng g⁻¹ and represent means with s.e.m. of values obtained from twelve to twenty-eight determinations per group performed in three to seven experiments. Each determination was carried out with one single whole brain or with pools of two to three brain parts.

Significance (compared with corresponding controls).

† $P > 0.05$; all other values, $P < 0.01$ (Student's *t* test).

ring in non-operated animals (Table 1). T_3 (20 μ g kg⁻¹) administered intraperitoneally (i.p.) to normal rats caused a rise of MOPEG in cerebral cortex, hypothalamus and mesencephalon plus medulla oblongata which was less pronounced than that due to TRH. In the 'rest of the brain' a similar increase was found after T_3 and TRH administration.

Since TRH did not change rectal temperature, the TRH-induced increase of cerebral MOPEG was probably not due to hypothermia in which noradrenaline turnover is accelerated¹⁵. An inhibition of the clearance of MOPEG from the brain is also unlikely, since other amine metabolites (homovanillic acid and 5-hydroxyindoleacetic acid), which are thought to be cleared by a similar transport mechanism as MOPEG¹⁰, were not affected by TRH. Therefore, the TRH-induced increase of MOPEG in the brain is rather due to an enhanced release of noradrenaline with consecutive catabolism of the amine to the glycol. This is confirmed by histofluorimetric experiments. Thus, the α -methyl-*p*-tyrosine-induced diminution of the green fluorescence specific for catecholamines was accentuated by TRH in the hypothalamus and the cerebral cortex which mainly contain noradrenergic fibres (Constantinidis *et al.*, in preparation).

Intraperitoneal injection of 10 mg kg⁻¹ TRH 1 h before intraventricular administration of L-3-¹⁴C-tyrosine enhanced the accumulation of ¹⁴C-noradrenaline formed in the whole brain within 1 h (controls: 1,393 \pm 55 c.p.m. g⁻¹, TRH-treated: 1,600 \pm 62 c.p.m. g⁻¹; $P < 0.02$, $n = 25$). This indicates an increased synthesis of cerebral noradrenaline which probably compensated for its enhanced release since the cerebral content of the endogenous amine remained unchanged. On the other hand, TRH did not influence the accumulation of ¹⁴C-dopamine in the brain (controls: 4,291 \pm 198 c.p.m. g⁻¹; TRH: 4,433 \pm 296 c.p.m. g⁻¹; $P > 0.05$, $n = 15$) in agreement with the fact that the hormone has no effect on endogenous homovanillic acid (see above). These findings indicate that TRH enhances the turnover of noradrenaline in the rat brain. The potentiation by TRH of the behavioural changes caused by L-dopa plus pargyline in hypophysectomised mice¹⁷ might be connected with this effect. Since TRH also acted in thyroidectomised rats, a mediation by the hypophyseothyroid axis does not seem to be a major mechanism in the acceleration of noradrenaline turnover. Nevertheless, as indicated in the experiments with T_3 , a contributing role of this hormone in normal animals cannot be excluded.

In conclusion, TRH probably causes an activation of noradrenergic neurons in the brain. This effect might be connected with the antidepressant action of the tripeptide in man and if so, support the hypothesis of an involvement of noradrenaline in mental depressive states.

We thank Dr W. Lotz, Department of Experimental Medicine, F. Hoffmann-La Roche Co. Ltd, Basel, for the

determination of thyroxine in blood serum. TRH was synthesised by Drs D. Gillissen and R. O. Studer, Department of Chemistry.

Multiquantal release of acetylcholine in mammalian ganglia

IN the course of studies on synaptic transmission in the hypogastric ganglia of male guinea pigs it became apparent that in many ganglion cells repetitive stimulation of the hypogastric nerve at 1-Hz raised the frequency of spontaneous synaptic potentials from less than 1 min⁻¹ to about 1 s⁻¹. Many of these cells had only a single preganglionic fibre synapsing with them so that the spontaneous synaptic potentials arising from a single nerve could be readily observed. Blackman *et al.*¹ described large spontaneous synaptic potentials in this preparation and we decided to examine the amplitude distributions of spontaneous synaptic potentials

FIG. 1 Amplitude distributions of spontaneous synaptic potentials in *a*, a cell whose single input was repetitively stimulated at 1 Hz; *b*, a single input cell in 15 mM K^+ .

recorded during repetitive stimulation (1Hz). Although 'spontaneous' synaptic potentials which were not time locked to the stimulus occurred occasionally during the evoked response, only those recorded after the membrane potential had returned to normal were selected for analysis.

A typical amplitude distribution for the spontaneous synaptic potentials recorded from a cell during prolonged repetitive stimulation (at 1 Hz) of its single input can be seen in Fig. 1*a*. The most striking feature is the appearance of a number of distinct groups in the distribution; if each group was treated as a separate distribution, means of $1.1(\pm 0.02)$, $2.0(\pm 0.02)$, $3.0(\pm 0.02)$, $4.0(\pm 0.03)$, $4.9(\pm 0.04)$ and $5.8(\pm 0.03)$ mV were obtained. This phenomenon was observed in every cell (seven cells with a single input) from which spontaneous synaptic potentials were recorded during repetitive stimulation. To determine whether the observations were due to some effect of stimulation, another method of raising the frequency of spontaneous synaptic potentials was used.

Blackman *et al.*² found that increasing the K^+ concentration in the bathing medium markedly increased the frequency of spontaneous synaptic potentials recorded from frog sympathetic ganglion cells. In the present experiments it was found that increasing the K^+ concentration from 5 mM to 15 mM raised the frequency of spontaneous synaptic potentials to about $1 s^{-1}$ even if the hypogastric nerve was not stimulated. Thus a large sample of spontaneous synaptic potentials could be recorded in a relatively short time. If the hypogastric nerve was stimulated the number of preganglionic inputs on the cell could still be determined. Figure 1*b* shows the amplitude distribution obtained in 15 mM K^+ from a cell with a single input. Several distinct groups can be seen, although samples of larger amplitudes were too small to allow analysis. If the groups were treated as separate dis-

tributions the means obtained were $0.5(\pm 0.008)$ mV, $1.0(\pm 0.02)$ mV, $1.5(\pm 0.02)$ mV, $2.0(\pm 0.06)$ mV, $2.4(\pm 0.06)$ mV.

This preparation clearly differs from the rat diaphragm, where Hubbard and Jones⁸ found that the amplitude distribution of spontaneous endplate potentials, although often skewed to higher amplitudes, showed no evidence of grouping about multiples of the modal amplitude. They concluded that the 'giant' spontaneous endplate potentials first described by Liley^{4,5} were due to larger than normal quanta. The 'giant' spontaneous endplate potentials at the rat neuromuscular junction however, have a different time course to the miniature endplate potentials⁶ and their frequency is unaffected by raised K^+ concentration or repetitive stimulation⁵.

The spontaneous synaptic potentials recorded in the hypogastric ganglia fit a multimodal amplitude distribution. There are at least two possible explanations of these results. (1) The quanta (or packets) of acetylcholine (ACh) stored in the preganglionic nerve terminals may be of a number of different sizes; or (2) spontaneous release of ACh may occur in multiquantal units.

The first explanation implies that the contents of the larger quanta would be approximately integral multiples of the contents of the smallest quanta. If a vesicle represents a quantum and the concentration of ACh in the vesicle is approximately uniform throughout the population of vesicles then their diameters should conform with the series 1, 1.26, 1.44, 1.59, 1.71 and soon with the diameter of the smallest vesicle taken as 1 unit. Any attempt to find evidence for a distribution of vesicle diameters with peaks at these relative values would be difficult as such measurements would be complicated by the uneven sectioning of vesicles inevitable in electron-microscopy. A quantitative study of the diameter and density of vesicles in the nerve terminals in the hypogastric ganglia would be necessary to completely eliminate this hypothesis.

Multiquantal spontaneous synaptic potentials have been described in the chick ciliary ganglion⁷ and in the parasympathetic ganglion cells of the septum of frog heart⁸. Martin and Pilar⁷ proposed that the spontaneous release of a single quantum created a small but finite probability that a second quantum would be released virtually simultaneously, the 'drag' hypothesis. They were able to fit the amplitude distribution of spontaneous synaptic potentials to a Poisson distribution by calling a unit response a failure and a double response a single and calculating a 'quantal content' of the 'dragged', synaptic potential. In the present experiments, however, no good fit could be obtained to either a Poisson or a binomial distribution using the 'drag' hypothesis. Dennis *et al.*⁹ were able to fit their data with a model based on the availability of release sites; however, their analysis could not be applied to the present experiments as no evidence was available to the maximum number of quanta which could be spontaneously released.

The quantum contents of subthreshold evoked synaptic potentials in most cells of the superior cervical ganglion⁹ and the sympathetic chain ganglia¹⁰ of guinea pigs do not appear to fit a Poisson distribution. In these preparations large spontaneous synaptic potentials can be observed and it is possible that the mechanism responsible for the large spontaneous synaptic potentials is also involved in the evoked release. Large increases in the frequency of spontaneous synaptic potentials due to repetitive preganglionic stimulation have, so far, only been observed in cells with 'strong fibre' type input¹; such input always initiates an action potential obscuring the evoked synaptic potential. By raising the Mg^{2+} : Ca^{2+} ratio in the bathing solution the amount of ACh released by a single impulse can be reduced and the quantal content of individual synaptic potentials could then be measured. Altering the Mg^{2+} : Ca^{2+} ratio, however, may

change the amplitude distribution of the spontaneous synaptic potentials⁸ and an examination of the ionic basis of both the spontaneous and the evoked release mechanisms will be necessary to complete this analysis.

The occurrence of large spontaneous synaptic potentials during low frequency repetitive stimulation could be of significance in the function of autonomic ganglia. Most autonomic ganglia receive tonic synaptic input from the central nervous system, *in vivo*¹¹, or from neurones in the periphery¹² and the cells in these ganglia receive input from many preganglionic nerve fibres¹³⁻¹⁵. In most cells, summation of synaptic potentials is necessary to excite an action potential and so if spontaneous synaptic potentials occurred of comparable amplitude to the evoked synaptic potential these might well be a significant factor in determining the firing pattern of cells in these ganglia. Large spontaneous synaptic potentials have been observed in many mammalian ganglia receiving multiple inputs, for example, guinea pig sympathetic chain¹⁰, guinea pig superior cervical ganglion⁹ and guinea pig inferior mesenteric ganglion (J. C. Bornstein, unpublished). Thus the output of a ganglion cell may depend not only on activity in the preganglionic nerves but also on the frequency of the spontaneous synaptic potentials released by these nerves. This seems to depend on the past activity of the nerve terminal.

Effects of β adrenergic blockade on plasma catecholamines in exercise

It is well established that physical exercise causes an increase in sympathetic activity, as shown by rises in the levels of plasma and urine catecholamines¹. This increase in endogenous adrenergic activity can be used to study the effects of sympathetic stimulation. Such studies usually compare a control situation with one in which either α or β adrenergic receptor activity is blocked pharmacologically, thereby allowing study of both the blocked and unblocked receptors. Beta blocking drugs have been used in this way to study changes in carbohydrate metabolism², free fatty acid metabolism³, and blood coagulation and fibrinolysis⁴ induced by exercise.

It has previously been assumed that because adrenergic blocking drugs act by blockade of the receptors, they do not affect the release of the catecholamines, and thus the magnitude of the sympathetic responses. A recent study⁵ has shown, however, that animals subjected to haemorrhagic shock under medication with α and β adrenergic blocking drugs in combination had lower levels of plasma catecholamines than the control animals in spite of an equivalent degree of blood loss and hypotension. Demonstration that single adrenergic receptor blockade also altered the extent of the sympathetic response in a stress situation would be of considerable importance, for in studies involving the use of

adrenergic receptor blocking drugs the unblocked receptor could be subjected to different degrees of adrenergic stimulation in the control and test situations. This would invalidate the current assumption that the extent of the sympathetic response is the same in both situations. This study reports the effect of three β adrenergic blocking drugs on the extent of the sympathetic response induced by exercise.

Five healthy males aged between 28 and 37 were studied at weekly intervals for four weeks. On each occasion the subjects had a light breakfast at 0800 h, and then reported to the laboratory at 1000 h. After resting on a couch for 15 min each was seated in a chair to allow removal of blood by venepuncture from an antecubital vein.

Each subject then exercised at 1,050 kilopond M min⁻¹ for 5 min. on a bicycle ergometer. On the first occasion the subjects exercised following the oral administration 2 h previously of 120 mg of oxprenolol (Trasicor, Ciba). In the second week, the experiment was repeated without medication and in the remaining two weeks the subjects were premedicated with 120 mg propranolol (Inderal ICI) and 12.5 mg Pindolol (LB46, Sandoz) respectively.

Immediately following exercise, blood was again taken from an antecubital vein with the subject in a sitting position. Blood samples were immediately put into 10 ml lithium heparin tubes, centrifuged and the red cells separated. The resulting plasma was frozen at -70°C and subsequently analysed by the trihydroxyindole fluorometric method for plasma catecholamine concentrations⁶. Measurements were made of total catecholamines and noradrenaline, the adrenaline level being deduced by difference. The plasma was also analysed for concentrations of the β blocking drugs to confirm adequate β blockade.

Comparison of the resting pre-exercise catecholamine concentrations in the medicated and non-medicated groups showed no difference in the noradrenaline levels. Adrenaline levels in the medicated groups were, however, marginally higher than those in the non-medicated group, but the dif-

ference was not statistically significant. Exercise in both groups caused rises in both plasma adrenaline and noradrenaline levels (Table 1). The extent of the response was however different in the β blocked and control groups. For example, whereas in the non-medicated controls noradrenaline

FIG. 1 Effects of adrenergic blockade on plasma adrenaline response to exercise. *a*, Control; *b*, oxprenolol; *c*, propranolol; *d*, LB 46.

rose from a mean of $0.52 (\pm 0.06)$ to $0.57 (\pm 0.13) \mu\text{g l}^{-1}$, and adrenaline rose from a mean of $0.14 (\pm 0.16)$ to $0.23 (\pm 0.26) \mu\text{g l}^{-1}$, the same workload in the group medicated with propranolol produced a rise of noradrenaline from $0.52 (\pm 0.08)$ to $0.78 (\pm 0.21) \mu\text{g l}^{-1}$ and a rise in adrenaline from $0.16 (\pm 0.13)$ to $0.64 (\pm 0.35) \mu\text{g l}^{-1}$. Subjects medicated with oxprenolol and pindolol showed similar results (Table 1, Fig. 1). The difference in the adrenaline response in the β blocked groups and the non-medicated control group was statistically significant ($P > 0.05$). Although the levels of noradrenaline exhibited a similar trend (Fig. 2), the values obtained in the medicated groups were not significantly different from those in the non-medicated group.

FIG. 2 Effects of adrenergic blockade on plasma noradrenaline response to exercise. *a*, Control; *b*, oxprenolol; *c*, propranolol; *d*, LB 46.

Evidence of adequate β blockade in the medicated groups was demonstrated both by a reduction in the degree of exercise-induced tachycardia evident in the nonmedicated group

and by measurement of the plasma levels of all three β blocking drugs.

Most of the volunteers found it more difficult to exercise when medicated with β blocking drugs, but in only one case was there any profound circulatory change. This was observed in one individual medicated with pindolol, who at the end of the period of exercise showed marked bradycardia, cutaneous vasoconstriction and syncope. It is interesting that his rises in adrenaline and noradrenaline (from 0.36 to $1.95 \mu\text{g l}^{-1}$ and from 0.63 to $1.47 \mu\text{g l}^{-1}$) were the greatest recorded in this study.

In all forms of exercise the sympathetic nervous system is activated to a greater or lesser degree. The stimuli for this sympathetic response include baroreceptor activation, pain and psychological factors. These results in the release of adrenaline and noradrenaline from the adrenal medulla and nerve endings respectively.

Von Euler⁷ considers that the increase in plasma catecholamines probably reflects compensatory adrenergic activity in non muscular vascular beds, designed to counteract the effects of the vasodilatation induced by exercise in the muscle beds. Activation of the vasomotor centre in exercise is *via* blood pressure homeostatic reflexes⁸. In addition, however, emotional stress occasioned by hard physical exercise could also contribute to the extent of the adrenergic response.

Our studies have demonstrated for the first time a significant difference in the extent of the adrenergic response to exercise in subjects under β adrenergic blockade. The exact reason for the excess adrenergic activity is not clear. The reliability of the fluorometric assay used is now established⁹ and the pre-exercise values in all four groups show that the β blocking drugs themselves have not interfered with the accuracy of the assay. This same observation also confirms that the results cannot be attributed to intrinsic adrenergic activity of the β blocking drugs. Account must be taken of the possible contribution of psychological stimuli to the increased adrenergic response under β blockade, for there is no doubt that in most cases, the volunteers found it more difficult to carry out the workload when medicated with β blockers. Anxiety in the pre-exercise period can, however, be excluded by examination of the resting catecholamine levels.

The most likely cause for the increased adrenergic response in the β -blocked individuals is an exaggeration of the compensatory response described by von Euler⁷. Beta blockade reduces the compensatory increase in cardiac output that normally occurs in exercise by 17% (ref. 10) and this, in association with dilatation in the muscle beds, can lead to a fall in arterial blood pressure¹¹ which activates an increased sympathetic response.

Irrespective of the cause of this increased adrenergic response to exercise under β blockade, the observation is of considerable significance for two reasons. First, it demonstrates that in experiments using exercise to stimulate sympathetic nervous activity to investigate its circulatory or metabolic effects, β adrenergic blockade alters the degree of the adrenergic response, and consequently the stimulation of the unblocked α receptor. Second, the information is of significance in the management of patients on treatment with β adrenergic blocking drugs. These drugs are widely used in the treatment of angina pectoris and hypertension. Our findings indicate that patients being so treated should be warned against undertaking sudden vigorous exercise, as this might result in an excessive adrenergic response which could have deleterious effects.

Beta adrenergic blockade with propranolol, oxyprenolol, or pindolol significantly increases the adrenergic response to exercise as judged by measurement of plasma catecholamine concentrations.

This work is supported by grants from the British Heart Foundation. We thank Ciba Ltd for measuring the plasma

concentrations of oxprenolol, and Sandoz Ltd for arranging statistical advice.

Glutamate antagonists at a crayfish neuromuscular junction

As Kravitz *et al.*¹ have pointed out, glutamic acid is at present the only candidate for the excitatory transmitter at crustacean neuromuscular junctions. The evidence is that^{1,2} glutamic acid is the most potent excitatory substance present in the crustacean central nervous system (CNS), whole peripheral nerves and isolated excitatory axons^{1,3-5}; that the glutamic acid content in nerve extracts accounts for the whole of their excitatory activity on crustacean muscles¹, and that the receptors to glutamate are localised at the same junctional spots as the receptors to the natural excitatory transmitter⁶. Also, both glutamic acid and the natural transmitter produce similar changes in the permeability of the postjunctional muscle membrane⁷⁻⁹ and in spite of a large background leakage, a significant release of glutamic acid can be evoked by stimulation of excitatory nerves¹. There is also a selective uptake of glutamic acid at the neuromuscular junction which could provide an inactivation mechanism¹⁰. There is, however, no information on whether glutamate receptors have the same pharmacological properties as the receptors of the natural excitatory transmitter.

The main object of the work reported here has been to screen a series of compounds for a specific antagonist to glutamic acid. We have found some drugs which specifically block both the responses to iontophoretically applied glutamate and the excitatory junctional potentials (EJPs) recorded from the same crayfish muscle fibres.

We used the slow flexor abdominal muscle fibres¹¹ from the crayfish *Procambarus clarkii*. These muscles are located in the anterior wall of each abdominal segment, each side of the midline, just beneath the integument. One insertion is on a sternite and the other on an integumental ridge. The superficial layers of the anterior wall of an abdominal segment were removed together with both sternites limiting the segment and placed in a perspex chamber through which van Harreveld's solution was continuously circulated. The

integument covering the muscle was first excised to allow the transillumination of the muscles and the two sternites were then fixed to the bottom of the chamber, without stretching the muscle fibres, in order to expose the posterior face of the slow flexor muscles. Single fibres were impaled with two independent KCl-filled micropipettes separated by 100-200 μ m. One pipette was used for recording through an amplifier of unit gain connected to a 280 Brush pen recorder; the other was used to pass constant current pulses across the membrane for measuring the input resistance of the fibre and/or steady current for setting the membrane potentials to desired levels. Glutamate ions were applied iontophoretically on to the muscle fibres as an anion from a third micropipette filled with a 2 M monosodium glutamate solution at pH 8.0. When necessary, GABA was also applied iontophoretically as a cation, from another pipette filled with a 1 M GABA solution at pH 3.5.

To study the effect of the drugs on the EJPs advantage was taken of the fact that the slow flexor abdominal muscles fibres receive synaptic inputs from several 'spontaneously' firing motoneurons¹². A whole abdomen preparation was therefore set up in the chamber, the integument of one of the segments was removed and the fibres were impaled with a micropipette. In this preparation, the connections of the nerve cord with the muscles remained intact, and a barrage of 'spontaneous' EJPs could be recorded (Fig. 1). In all the experiments, the drugs tested were dissolved in the van Harreveld solution and perfused to the preparation.

When glutamate is applied to a slow flexor muscle fibre three main sensitive regions, separated by insensitive areas, are revealed: one at each end of the fibres near the insertions and a large field in the central parts of the fibre. The responses to glutamate consist of fast depolarisations (Fig. 2a),

Fig. 1 Isolated crayfish abdomen preparation. The EJPs recorded from an abdominal slow flexor muscle fibre result from the 'spontaneous' firing of several motoneurons. In each horizontal row, the same synaptic activity was recorded at two different speeds. *a*, EJPs discharge when the preparation is bathed in a normal medium. *b*, After perfusing to the preparation a 10^{-3} M solution of L-glutamic acid γ -methylester, the amplitude of the EJPs is decreased. *c*, Decrease in the amplitude of the EJPs is almost complete after the concentration of the antagonist to 10^{-2} M. Notice in *b* and *c* that there is no evident alteration of the frequency of discharge of the EJPs. *d*, Recovery after prolonged washing.

easily desensitised by repeating the iontophoretic application, and showing the same time course and properties as the ones described by Takeuchi and Takeuchi⁶ in the dactyl muscles.

Of 56 drugs (glutamic acid structural analogues, enzyme inhibitors, drugs showing effects on other synapses), eight substances were found to block the glutamate responses (Table 1). The mechanism of their blocking action was analysed and their relative potency evaluated. The γ -methyl ester of L-glutamic acid (L-Glu- γ -ME) was the most potent of the drugs tested, followed by other methyl and ethyl esters of L-glutamic acid, piperazine, strychnine and phenylurea. The effect of these compounds on the input resistance of the muscle fibres was tested and only phenylurea and coumarin were found to increase consistently the resting membrane conductance. This effect was probably independent of the blocking effect since after these substances were

TABLE 1 Eight substances which block the glutamate response

Compound	Relative blocking efficacy	Effect on membrane conductance	Effect on GABA receptors
L-glutamic acid γ -methyl ester	100	No	No
L-glutamic acid dimethyl ester	90	No	No
L-glutamic acid monoethyl ester	60	No	No
L-glutamic acid diethyl ester	50	No	No
Piperazine	90	No	Blocks
Strychnine	80	No	No
Phenylurea	80	Increases	No
Coumarin	60	Increases	No

FIG. 2 A series of iontophoretic applications of glutamate on to an abdominal slow flexor muscle fibre of *Procambarus*. The vertical bars mark the duration of the application. At the right of the recordings, a series of electrotonic potentials obtained after each glutamate response by passing current pulses across the fibre membrane. *a*, Glutamate response and the electrotonic potential in a normal medium. *b*, Glutamate response decreases in amplitude after perfusion to the preparation of a 10^{-3} M solution of L-glutamic acid γ -methyl ester. *c*, Response to glutamate is almost blocked under action of a 2×10^{-3} M solution of the antagonist. In both *b* and *c* there is no change in the amplitude of the electrotonic potentials, that is, of the membrane resistance. *d*, Onset of recovery of the glutamate response after removal of the blocking agent.

removed the membrane input resistance rapidly recovered its control values, whereas the recovery of the glutamate responses was much slower. Because of these non-specific effects on the membrane conductance these two substances were unsuitable for analysing the synaptic inputs.

In addition, piperazine, which did not affect the muscle membrane conductance, blocked the responses not only to glutamate, but also to GABA. We considered that this made piperazine not worth further investigation. Finally, strychnine was found to be an effective antagonist of glutamate on these muscle fibres at concentrations of 10^{-3} to 10^{-2} M, without showing effects on the membrane conductance or the GABA responses. But since strychnine has been shown to block other receptors in other preparations (glycine receptors in vertebrate spinal neurones¹³ and acetylcholine receptors in molluscan neurones¹⁴) and to interfere with the release of transmitter in vertebrates¹⁵ and invertebrates¹⁶, we did not use it in the experiments on the EJPs.

The most suitable drugs for such analysis were therefore the esters of L-glutamic acid, in particular L-Glu- γ -ME. Figure 2(*b* and *c*) shows that at concentrations up to 2×10^{-3} M it blocks almost completely the response to glutamate without affecting the membrane conductance of the muscle fibre. Even at concentrations of 10^{-2} M no effect on the input resistance was observed. The recovery shown in Fig. 2*d* is only partial but after prolonged washing the effect was totally reversible. On the other hand, the same concentrations of antagonist did not affect the responses of the fibres to the iontophoretic application of GABA (Fig. 3*b*).

Haldeman and McLennan¹⁷ working with spinal and cuneate neurones found that the diethyl ester of L-glutamic acid was the most potent blocker of the series, whereas the methyl esters had agonistic effects. This reversed pattern suggests that the receptors in the vertebrate CNS and on crustacean neuromuscular junctions could be different.

The effects of L-Glu- γ -ME were assayed in the 'spontaneous' EJPs recorded in the slow flexor muscle fibres in an *in vitro* abdomen preparation (see above). In Fig. 1*a* a barrage of EJPs was recorded in these fibres at two different speeds. When L-Glu- γ -ME was applied to the preparation at concentrations of 10^{-3} M (Fig. 1*b*) and 10^{-2} M (Fig. 1*c*) the amplitude of the EJPs gradually decreased without evident alteration of their frequency. This effect was reversible (Fig. 1*d*) after prolonged washing.

These experiments show that L-Glu- γ -ME blocked both the responses to the iontophoretic application of glutamate and the EJPs recorded from the same muscle fibres, without altering the input resistance of the fibres, the frequency of the neuronal firing or the conduction velocity of the motor axons. Nevertheless, the possibility that this compound acts on the quantal content of the EJPs must be investigated in further experiments.

We conclude that in spite of its low affinity for the glutamate receptors, L-Glu- γ -ME is a highly specific antagonist of glutamate on the crayfish neuromuscular postjunctional mem-

FIG. 3 L-glutamic acid γ -methyl ester does not affect the GABA responses of an abdominal slow flexor muscle fibre. *a*, Control hyperpolarising response to the iontophoretic application of GABA. *b*, GABA response remains unchanged after perfusing to the preparation a 5×10^{-3} M solution of the glutamate antagonist.

brane. The observation that it also blocks, very probably at the postsynaptic level, the generation of the EJPs is a new argument in favour of a transmitter role of glutamate in these neuromuscular junctions.

Trichodermin resistance—mutation affecting eukaryotic ribosomes

GENETIC studies of ribosomes in prokaryotes such as *Escherichia coli* have been facilitated by the use of mutants resistant to antibiotics; mutations which affect either subunit of the ribosome are known¹. In eukaryotes, genetic informa-

TABLE 1 Cross resistance between trichothecenes

Drug	CLP-1 (resistant) 100% = 13.2	A224A (sensitive) 100% = 63.1
Control		
Trichodermin (20 $\mu\text{g ml}^{-1}$)	100%	95%

S. cerevisiae strains A224A and CLP-1 were grown on a medium containing yeast extract-peptone-dextrose buffered to pH 5.8 with sodium succinate to about 3×10^7 cells ml^{-1} . The cells were collected, washed with ice-cold distilled water, resuspended in an equal volume of 100 mM Tris-50 mM KCl-5 mM Mg acetate-1 mM DTT (TKMD), and passed two times through a French pressure cell at 16,000–20,000 pound inch^{-2} . The suspension was centrifuged twice for 10 minutes at 18,000 r.p.m. in an SE-12 rotor (34 Kg). The top two-thirds of the supernatant was centrifuged for 2 h at 42,000 r.p.m. in a Ti50 rotor. The supernatant was removed avoiding the fluffy layer which was poured off and the pellet was resuspended in TKMD and 4 M NH_4Cl was added to a final concentration of 0.3 M and stirred for 30 min. The ribosomes were pelleted at 42,000 r.p.m. for 2 h, resuspended in TKMD and dialysed overnight against TKMD containing 0.6 mM β -mercaptoethanol. A supernatant fraction was prepared by precipitating the postribosomal supernatant with 70% ammonium sulphate and collecting the precipitate at 34,000 g for 20 min. The pellet was resuspended in one-third the original volume of TKMD and dialysed overnight in TKMD containing β -mercaptoethanol. Phenylalanine incorporation was performed in mixtures containing 50 mM Tris-HCl, pH 7.6, 100 mM KCl, 18 mM Mg acetate, 500 $\mu\text{g ml}^{-1}$ tRNA, 3.3 mg ml^{-1} creatine phosphate, 260 $\mu\text{g ml}^{-1}$ creatine kinase, 2 μM ^{14}C -phenylalanine ($10 \mu\text{Ci ml}^{-1}$), 1.0 mM ATP, 0.1 mM GTP and 500 $\mu\text{g ml}^{-1}$ poly (U). Incubations were carried out at 30°C for 30 min and terminated with 1 ml of 10% TCA. The reaction mixtures were filtered through GF/C glass fibre filters and washed five times with 3 ml of 5% TCA. Filters were dried and counted in a toluene-based scintillation fluor. Figures are expressed as percentage of control activity which is given in picomol of ^{14}C -phenylalanine incorporated.

tion on the translation apparatus has come mainly from studies of temperature-sensitive mutants^{2,10}, and also cycloheximide resistance, which is known to be a property of the 60S subunit³. Recent studies with resistance to the alkaloid cryptopleurine have shown that *Saccharomyces cerevisiae* strains resistant to this compound have altered ribosomes⁴.

Trichodermin

Trichodermin is a fungal toxin which belongs to the general class of 12, 13-epoxytrichothecenes; these compounds inhibit protein synthesis in eukaryotes but not prokaryotes (for a review, see ref. 5). The mode of action of these compounds on protein synthesis *in vivo* has been studied and the trichothecenes can be divided into two classes on this basis⁶. Some of the trichothecenes (such as verrucaric A and nivalenol) inhibit a step related to or shortly after initiation, while trichodermin affects elongation and/or termination by interfering with the peptidyl transferase reaction on the ribosomes. We now report the isolation of a spontaneous mutant of *S*

TABLE 2 Localisation of resistance to nivalenol on *S. cerevisiae* ribosomes

(a)	Ribosomes	Supernatant	Control	+ Nivalenol (5 μ g ml ⁻¹)	% Activity
	A224A	A224A	82.4	19.0	23
	A224A	CLP-1	51.5	17.0	33
	CLP-1	A224A	33.5	32.8	98
	CLP-1	CLP-1	8.9	8.7	98
(b)	Subunit source				
	40S	60S			
	A224A	A224A	69.8	22.3	32
	CLP-1	CLP-1	33.7	34.4	102
	CLP-1	A224A	84.2	23.6	28
	A224A	CLP-1	31.2	31.2	100
	A224A	—	1	—	—
	—	A224A	4.2	—	—
	CLP-1	—	3.9	—	—
	—	CLP-1	6.0	—	—

Ribosomal and supernatant fractions were prepared as described in the legend to Table 1. Free ribosomes were prepared as described by van der Zeijst *et al.*⁹ and subunits were separated by centrifugation through a 10–30% sucrose gradient in 50 mM Tris-HCl, pH 7.6 containing 500 mM KCl and 5 mM Mg acetate for 7 h at 22,500 r.p.m. in a SW-27 rotor at 15° C. The supernatant fraction used with the subunits was derived from the wild-type sensitive strain A224A. 0.13–0.20 A 260 units of each subunit was used in reaction. The incorporation of phenylalanine was assayed as in Table 1. Activity is expressed as total picomol of ¹⁴C-phenylalanine incorporated. An independently isolated mutant, CLP-8, gave similar results.

cerevisiae A224A which is resistant to 20 μ g ml⁻¹ of trichodermin and show that this mutant has an altered 60S subunit.

Ribosomes and supernatant fractions from a strain sensitive to trichodermin, A224A, and a strain resistant to trichodermin CLP-1, were prepared and tested for their response to trichodermin and related trichothecenes in Poly(U)-directed polyphenylalanine synthesis. Ribosomes from the sensitive strain were strongly inhibited by several of the trichothecenes (Table 1). In agreement with previous reports⁷, trichodermin was not an effective inhibitor of the poly(U) system. Polypeptide synthesis in extracts of the trichodermin-resistant strain was markedly resistant to nivalenol, and since trichodermin is not an effective inhibitor in the poly (U) system, we have used nivalenol to determine which component of the protein-synthesising system is altered in the strain resistant to trichodermin.

Table 2 shows that resistance to nivalenol in *S. cerevisiae* CLP-1 was associated with the ribosomes; specifically with the 60S subunit. As a further demonstration that trichodermin resistance was associated with the ribosomal fraction of strain CLP-1, we tested the effect of trichodermin on

puromycin-induced release of nascent peptide chains on polyribosomes (puromycin reaction). In the sensitive strain the puromycin reaction was inhibited in the presence of trichodermin, whereas the puromycin reaction on polyribosomes of *S. cerevisiae* CLP-1 was substantially resistant to trichodermin (Table 3).

As well as providing important genetic information on the structural components of ribosomes, antibiotic-resistant mutants also provide clues to the mode of action of an inhibitor. The demonstration of trichodermin resistance as a property of the 60S subunit of resistant strains is consistent with the notion that trichodermin inhibits the peptidyl transferase reaction (a property of the 60S subunit⁸). It has been suggested previously that it could act by preventing access of the aminoacyl-tRNA acceptor to the peptidyl transferase centre⁷.

Genetic studies have shown *S. cerevisiae* to have at least 17 chromosomes. Cycloheximide resistance, *cyh2*, a property of the 60S subunit, maps on chromosome VII² and cryptopleurine resistance, *cry1* (another ribosomal alteration) maps on chromosome III (ref. 4 and P. Grant, unpublished observations). Genetic analysis of CLP-1 indicates that trichodermin resistance is not linked to *cyh2* or *cry1*. Although there is no evidence that these mutations affect ribosomal proteins and not rRNA or modifying enzymes, the organisation of structural genes for ribosomes in simple eukaryotes such as *S. cerevisiae* may prove to be different from the ribosome gene 'cluster' found in prokaryotes such as *E. coli*. Recently, the genes for ribosomal proteins of *Drosophila* have been mapped and all ribosomal protein genes may be located within a 'cluster' in this eukaryote¹². In addition, the *Drosophila* ribosomal protein genes are linked to rRNA genes. In *S. cerevisiae* it has been shown that 70% of the rRNA is coded for by chromosome 1 (ref. 13). Trichodermin resistance is not linked to *adel* on this chromosome; therefore none of the three mutations, cycloheximide resistance, cryptopleurine resistance, or trichodermin resistance, which are known to affect ribosomes in *S. cerevisiae* are linked to the known rRNA genes or to each other.

This investigation was supported by a grant from the National Institutes of Health. Drs W. O. Godtfredsen, F. Strong and C. Tamm provided gifts of fungal toxins.

CLP-1			
Polysomes	3.2, 1.1	2.3, 0.7	30.9

Yeast spheroplasts were prepared as described by Hartwell and McLaughlin¹⁰, substituting 1 M sorbitol for the 0.4 M MgSO₄. They were collected by centrifugation, resuspended in TKM and lysed with 0.5% sodium deoxycholate and 1% Brij 58 (Atlas Chem. Co.). The lysate was layered on a discontinuous gradient of 20% sucrose–60% sucrose in TKM, and centrifuged at 35,000 r.p.m. for 4 h in the Ti50 rotor. The pellet was resuspended in TKM. Assays were performed as described by Pestka *et al.*¹¹ except that GF/C glass fibre filters were used to collect the insoluble peptidyl-puromycin fragments. Trichodermin was present as indicated at 20 μ g ml⁻¹. Reactions were incubated at 30° C for 5 min. Activity is expressed as total picomol of ³H-puromycin incorporated into peptidyl-puromycin.

book reviews

Animal interactions

Models in Ecology. By J. Maynard Smith. Pp. xii+146. (Cambridge: London, January 1974.) £3.70; \$10.50.

Ecology suffers from a surfeit of fascinating, but apparently unrelated observations, superimposed upon an acute shortage of general theories. An inevitable consequence has been the growing importance of general, precise, rather simple models which may provide insights into the workings of the real world, without its baffling complexity. This book provides a particularly good example of the approach, although it is by no means a general account of the ways in which models have been, and are being used in ecology. The problems which it chooses to examine range from predator-prey systems (chapters 2, 4, 6 and part of 11), the importance of time delays in population dynamics (chapter 3), competition (chapters 5 and 9), stability and complexity (chapters 7, 8, 10 and 11) and territorial behaviour (12), with the underlying theme throughout being the problem of stability in ecological systems. Virtually all the models are in the form of deterministic differential equations, the justification for using deterministic models being discussed briefly in chapter 1. In a comparatively small number of instances difference equations are used, while Leslie matrices are mentioned so briefly in chapter 3 that their inclusion hardly seems worthwhile.

As Maynard Smith points out, "the purpose of mathematics is to render the assumptions lying behind the arguments more explicit". But that is only the first step, albeit an important one. Conclusions derived through use of mathematics, and hence the assumptions themselves, should obviously be tested repeatedly against the real world, and even more importantly the models should suggest new insights and suggest new observations that are worth making. There are a disappointingly few places in this book where really new insights emerge, although it provides additional information and very useful summaries of a number of previously fairly well worked ideas. Material that is substantially new is to be found in chapter 6, which considers the effect of migration between sub-populations on the stability of predator-prey systems. It is a great pity that the logic used in setting up the model (pages 75-83) is not more fully explained. It seems to contain some cu-

rious assumptions, including the one that the addition of predators will make the prey in a subpopulation reach a larger population size faster than would be the case in the absence of predators. This does not seem reasonable. It is also a pity that no attempt has been made to find an analytical solution to the migration models, at least for the case of the simple model.

Chapter 10 includes a new analysis of a simple food web which attempts to provide a partial answer to the important question of how the number, and strengths, of the connections may influence the stability of the component populations. Again, an analytical solution is not attempted (and in this case one may not exist), but a simulation provides some interesting conclusions. Finally, chapter 12 provides a particularly good example of how an extremely simple model (in this case concerned with the influence of territorial behaviour on population density in birds) can provide some very interesting new insights into a well studied, but little understood, phenomenon.

In a number of other places in the book, the analysis may not be particularly new, but what it does do is explain well the main features of, or drawbacks and advantages in the types of analysis used by other workers. For example, it has some interesting comments to make about the 'standard' competition equations, and it provides an excellent summary of the major drawbacks inherent in the application of statistical mechanics to community modelling. Despite the sophistication of the mathematics, efforts in this direction would seem to be totally misdirected.

One of the main problems with the book is the patchiness with which it makes successful contact with the real world. Indeed this is partially acknowledged by the author, and by itself is not a major criticism, unless the reader (in making the contact for himself) finds a number of the models inadequate. Thus, there are rather sweeping generalisations being made about predator-prey systems in general, that are based almost entirely on models of predators which feed on only one species of prey, without questioning whether this is actually typical of most real predators. The fact that it isn't is never mentioned.

Nor are some of the actual attempts to relate observations and models equally successful. Some, like the analysis of Nicholson's blowflies in chapter 3 seem

to be good, but others, like the attempts to relate the stability properties of community models to Elton's and Watt's observations seem to lose sight of the obvious point that Elton and Watt are largely talking about population fluctuations, and the models are dealing with neighbourhood stability. These are not necessarily the same thing. Until ecologists build community models which consider global stability, and until they have experimental data that show whether the fluctuations one observes in nature are really unstable, or whether they merely represent, say stable limit cycles, movements towards equilibria with long damping times and continual disturbance, or what have you, most of the elegant discussion on pages 112-5 is not relevant.

It is certainly not a book for someone without a fairly good grounding in ecology. Equally it is not particularly suitable for someone who wants to learn how to apply certain techniques. One could not, for example, find out how to go about solving the general neighbourhood stability properties of a differential equation model. What it does do is show how apparently complex ecological problems can often be approached by rather simple models, and how such models can be used to 'get the feel' of the problem. If it encourages more practicing ecologists to do this it will have served a useful purpose.

J. H. LAWTON

Mathematical magnetism

An Introduction to Electromagnetic Theory. By P. C. Clemmow. Pp. xi297. (Cambridge University: London, 1973.) \$10.

IN explaining his reasons for adding another text to the many which already deal with electromagnetism at undergraduate level, Dr Clemmow makes the point that competition from other topics in a widening curriculum leaves less time than formerly for a student to master the fundamentals of electromagnetism and this calls for a more crisp approach than has been usual. This idea determines both his choice of material and the manner of presentation. The material is pared down to theoretical essentials, very little being allowed in purely to illustrate or for reinforcement, while the style is disciplined and economical, making each point once only, and that in a rather austere mathematical way. Within this framework,

the route through the theory is not unconventional. Vector algebra and MKS units are used throughout and Maxwell's equations introduced fairly soon, to be followed by chapters dealing with electrostatics, magnetostatics, waves and properties of media. Each chapter is followed by a set of problems, mostly of the 'show that' variety—otherwise no answers are provided.

It is consistent with the author's aim that there are few concessions to any weakness in the reader. It is assumed that he is fully conversant with vector algebra and needs little assistance in visualising the significance of the equations. Magnetic field lines for example are mentioned first in Chapter 4 and so are not employed in the fairly lengthy discussion leading to Maxwell's equations in chapter 2. The approach of this discussion is again mathematical as opposed to physical. For instance, the equation $\text{div } B = 0$ appears as a consequence of $B = \text{curl } A$ rather than as a statement of the absence in nature of magnetic poles.

It is difficult to judge how big is the gap which the book is designed to fill. Well prepared students will appreciate the lack of distractions and the numerous mathematical points succinctly made. It would hardly be appropriate though for those, perhaps more typical students, who find they need to learn

mathematical methods and physical theory together and also need to surface frequently from abstract depths to reinforce new ideas with physical pictures and test them in the context of familiar practical applications.

S. CLOUGH

Raman spectra

The Raman Effect. Vol. 2: Applications. Edited by A. Anderson. Pp. xi+405-1033. (Dekker: New York, July 1973.) \$45.

THE initial impact of this book may well be governed by its price since \$45 is a particularly excessive sum to pay for a textbook. But on closer acquaintance it is seen to be rather less the extortion of funds from university libraries than it might appear since the book consists of two or three sub-books in the form of reviews, 100-200 pages in length, which are both authoritative and comprehensive.

The first chapter by Tobias gives applications of Raman spectroscopy to inorganic chemistry, describing experimental techniques and how to interpret results to obtain structural information. There are also sections on solution equilibria and fused salts and it provides a most valuable review. It is followed by a chapter on electronic Raman transitions from Koningstein and Mortensen. This is a very concise account, which contains the essentials of the use of the technique in identifying low-lying electronic states in crystals containing rare-earth ions. The next chapter is a treatise by Weber on high resolution Raman spectra of gases. This very complete account discusses the theory of rotational Raman, and its use in molecular structure determination. It also gives useful information on experimental techniques in detecting the weak signals characteristic of gas phase work.

Finally, there are two chapters on the spectra of crystals. A short introduction to the study of molecular crystals is given by Savoie who outlines the theoretical basis of the treatment of pure solids. This chapter mainly concerns crystals of simple molecules such as HCN and CF₄. The last chapter by Wilkinson is an outstanding review of the spectra of ionic, covalent and metallic crystals. Theoretical principles are lucidly explained in the early part of the chapter and the author then discusses assignments and experimental data for a large number of crystalline systems classified into different types. In each case the analysis is presented together with a discussion of available data. In addition there is a section on scattering from Landau levels, magnons and states other than phonons.

This collection of very authoritative articles will provide an invaluable refer-

ence text for workers in the field of Raman spectroscopy. The price of the book will ensure that few individuals will purchase it. This is particularly emphasised since this volume does not contain a chapter devoted to the general theory of the Raman effect and thus its companion volume is required. None the less it is a well produced book and it fills several gaps in the literature with authority.

A. J. McCaffery

Master class

Molecular Techniques and Approaches in Developmental Biology. Edited by Maarten J. Chrispeels. Pp. xii+306. (Wiley-Interscience: New York and London, October 1973.) £8.25.

THE mixed bag of articles making up this book originated in the La Jolla Summer Workshops on Molecular Techniques in Developmental Biology. Each chapter is based on a practical project run by an invited scientist, to teach the techniques used in his own research. The net result is a book which lacks coherence and covers only a limited amount of ground but, nevertheless, contains an enormous amount of very practical information, often in the form of step by step instructions with hints on how to adapt the method to other tissues. Obviously such a book can never be a real substitute for learning at the bench of a master and absorbing his or her approach towards developmental problems, but in the absence of opportunities for such personal contact it is certainly the next best thing.

The more prosaic of the eleven chapters deal with the fractionation of sub-cellular organelles, the separation of isozymes by gel electrophoresis and proteins by gel filtration, and the isolation of DNA from eukaryotic cells. Other chapters provide very detailed accounts of how to measure the number of progesterone receptor sites in rat uterus, how to calculate the real rate of RNA synthesis in sea urchin embryos incubated with ³H-adenosine by measuring the specific radioactivity of the ATP pool, and how to study changes in the population of transfer RNA species in developing tissues. The chapters I found most interesting were those by Pong and Loomis on the isolation of RNA polymerases from *Dictyostelium*, and by Bob Church on the theory and methodology of DNA-DNA and DNA-RNA hybridisation as applied to nucleic acids from cells of higher animals. The latter is a particularly lucid description of some very complex techniques and covers a lot of ground, including the increasingly important method of RNA-DNA hybridisation in a vast excess of DNA.

BRIGID HOGAN

THE HISTORY OF QUANTUM THEORY

Friedrich Hund

Professor at Göttingen University

Translated by Gordon Reece
M.Sc., Imperial College, London

Professor Hund — one of the few remaining scientists with a first-hand knowledge of the development of quantum theory in physics and chemistry between 1900 and 1927 — describes comprehensively and accurately the major discoveries, ideas and the people in this exciting period of scientific history.

matters arising

Waste and the Pacific

SIR,—The letter which appeared in *Nature* concerning the distribution of tar along latitude 35°N in the Pacific Ocean¹ raises the question of the cause of the pronounced peaks which occur.

One of the explanations advanced is that meanders in the Kuroshio current could be responsible for the distribution. If this were the case, the distribution would have peaks corresponding to the meander wavelengths, which are typically 200 km to 400 km (2° to 4° longitude). This is unlikely to be correct, since the three pronounced peaks are separated by distances of 2,000 km (20° longitude) and 1,300 km (13° longitude).

Another possible explanation of this distribution is that the intense Kuroshio current may generate a series of Rossby waves, which can propagate across the entire Pacific Basin².

In a numerical model recently developed by myself (to be published) a surface layer, 100 m deep and in an idealised basin, was subjected to a zonal

wind stress typical of winter in the Northern hemisphere. The energy dissipation was parameterised to occur

FIG. 1 The pattern of streamlines induced by a steady wind field in a hypothetical ocean basin, which extends from the equator to 60°N, and has a width of 60° longitude. The flow of the water is parallel to the streamlines and its intensity is proportional to the concentration of streamlines. The intense flow on the western edge of the basin is representative of the Kuroshio current in the North Pacific and the Gulf Stream in the North Atlantic.

over the continental shelves. The resulting steady circulation produced (Fig. 1) shows 'ripples' in the eastward flowing current between the subarctic gyre and the sub-tropical gyre (30°N to 55°N). The wavelengths in this particular example decrease from 1,300 km (13° longitude) in the western half of the basin to 600 km (6° longitude) in the east. The amplitude of meridional velocity at 35°N decreased from 8 cm s⁻¹ in the west to 4 cm s⁻¹ in the east.

I suggest, therefore, that the observed distribution of tar may be explained more satisfactorily in terms of the type of waves predicted by the model.

Yours faithfully,

obituary

G. P. Kuiper

GERARD PETER KUIPER died suddenly on December 24, 1973, after a long and greatly distinguished career of ardent devotion to astronomy. He has left his mark by his achievements in observational and theoretical research and in developing new instruments, and in many other ways—as a director and founder of research institutes, as a writer and editor in the grand manner, as from the outset a prominent collaborator in the NASA lunar and planetary programmes which he called “the greatest scientific venture of history.”

Kuiper was born on December 7, 1905 in the Netherlands. In 1933 he gained his doctorate in Leiden for a thesis on binary stars with the renowned Ejnar Hertzsprung as his adviser. He then went to work mainly on the same subject at Yerkes Observatory, where Otto Struve had assembled perhaps the most brilliant

team of young astronomers in existence. After spending the year 1935–6 at Harvard, Kuiper returned to Yerkes as a staff-member and, apart from civilian scientific war services—he had become a United States citizen in 1937—he remained until 1960, twice serving as Director of the Yerkes and McDonald Observatories 1947–49, 1957–60. He then moved to the University of Arizona in Tucson, where he founded and directed the Lunar and Planetary Laboratory and its Catalina Observatory with an armoury of large telescopes for planetary work. These included the well-known 61-inch high resolution telescope specially adapted for observations in the near infrared, one of the many fields in which Kuiper was a pioneer. He relinquished some administrative responsibilities in 1973, but at the time of his death he was planning fresh developments of his scientific work. In the United States and abroad, Kuiper received numerous hon-

ours for his contributions to astronomy; the Royal Astronomical Society elected him an Associate in 1951.

As long ago as 1937, Kuiper's paper on Hertzsprung-Russell diagrams of stellar clusters pointed the way to much subsequent empirical work on stellar evolution. His pioneering work with Stromgren and Struve on models for close binary stars initiated what is still one of the most lively branches of stellar astrophysics. His classical papers of 1938 on the empirical mass-luminosity relation and of 1942 on “the nearest stars” remained for over a decade the main compendia of empirical stellar parameters.

Kuiper's dominating lifelong interest was, however, the solar system. He discovered two new satellites Miranda (Uranus) and Nereid (Neptune), the atmosphere on Saturn's satellite Titan, and the asteroid that bears his name. From 1960 onwards he produced (with

collaborators) four successive atlases of the Moon, based first on observations from Earth and then from space vehicles, and these played a vital role in choosing sites for Apollo landings. All this effort was inspired by the hope of ultimately elucidating the origin of the solar system.

With the astronomer Barbara M. Middlehurst, Kuiper edited the two famous series *The Solar System* (four of its five volumes are published), and *Stars and Stellar Systems* (seven of its nine volumes are published). Indeed, astronomers have seemed to be more excited when a new Middlehurst-Kuiper volume appeared than they were when quasars or pulsars were discovered.

Announcements

Appointments

The Council of the University of Bristol has appointed D. C. Smith, of the Department of Agricultural Science of the University of Oxford, to the Melville Wills Chair of Botany.

Erratum

In the article "Fluctuations in oil flow before and after earthquakes" by E. Arieh and A. M. Merzer (*Nature*, 247, 534; 1974) the former author is at the Seismological Laboratory, Geological Survey of Israel, Jerusalem and the latter at the Department of Environmental Sciences, University of Tel Aviv.

Science beyond the fringe

It would have amazed the Victorian steadfasts of science how confused some of our attitudes towards science still are. Instead of the logical world they hoped for and tried to work in there is a discernible tendency for the public and even some practitioners of science to turn their backs on science and become preoccupied with the bizarre and the magical.

Mr Uri Geller is only the most recent to cast doubt in the public mind on the efficacy of rational explanation.

Archaeology is being plagued by a series of ideas which have achieved a following particularly among the young. Professor Glyn Daniel has tilted against some of these nonsenses in his fascinating and always readable editorials in *Antiquity*. At one end of the spectrum there are innocuous extrapolations of conventional ideas about the significance of Stonehenge. At the other there are people busily poring over Ordnance Survey maps of Britain plotting mythical alignments between ancient monuments and erecting fanciful hypotheses about prehistoric technological civilisations. It is not as if archaeology needs enlivening—the radiocarbon dating method has already done that and caused great excitement by requiring revisions of old ideas about the relationships between prehistoric peoples.

Elsewhere, Velikovsky is enjoying a revival at a time when real astronomy and the earth sciences have never been more fascinating. How long will it be before psychiatrists are inundated with requests for more research into possession by devils from people who have seen the film *The Exorcist*?

It is difficult to know why these beliefs beyond science have such a following and whether it is genuinely on the increase, but presumably it is closely tied to a prevailing mood of the questioning of established values and a disbelief that science has more than marginal relevance to the human condition.

All this can be fun, of course, but the danger is that taken too seriously it detracts from all the exciting things that are being achieved in, for want of a better description, conventional science based on conventional ideas about the way a scientific investigation should proceed. And, when pseudo-scientific ideas are finally demolished, as they usually are (although one of their characteristics is that they are long in the dying) their demise casts doubt in the minds of the general public about the value of scientific research in general.

Scientists want to fight this distressing drift from the scientific way of thinking, but are not being noticeably successful. Part of the answer is to make real science more attractive, and for this reason scientists should not be dismayed when they find professional communicators of scientific ideas using imprecise words in place of the

precisely-defined terms from the science laboratory. To capture and convey the excitement of modern science is the main thing. In this respect Professor Kurti's proposal for a code of professional etiquette, published in the November 1973 issue of *Physics Bulletin*, may turn out to stifle scientists' communications with the general public and have the opposite effect to the one he desires.

Nature has a responsibility in all this; a responsibility that perhaps more than anything else guides us in the choice of papers for publication. If the successes of the scientific world are to come through clearly to the general public and appear more compelling than myth and idle speculation does, it is also vitally necessary that the community of professional scientists should understand each other. If scientists, fully aware of the scientific method, find the work of others in different disciplines boring and unconvincing there is little chance that the layman will feel otherwise. As far as we are concerned a scientific journal can help by encouraging its authors to explain their findings in a way that will make them as widely accessible as possible. After all, if a paper is not understandable outside the branch of science in which it originated the paper might just as well be circulated and filed as a private report. It is also a continuous surprise to us how coquettish some authors are when it comes to an assessment of the implications of their findings. Often papers are sent to us describing new measurements of the levels of pollutants and contaminants, but with no estimates of whether the estimated levels are dangerous.

If we are more persistent than most journals in importuning authors to be briefer or blunter this is partly the deeply-felt view that brevity and clarity ultimately lead to wider dissemination of ideas and a greater understanding of science and sympathy with its objectives.

100 years ago

On the Word "Axiom"

IN reference to the controversy between Mr. Spencer and his reviewer about Sir I. Newton's calling his laws of motion "axioms," it is to be observed that there is a certain ambiguity in the word. "Axiom" is from ἀξίωμα (I demand), and would thus signify a first principle to be taken for granted. It does not, of course, carry with it the meaning of a necessary judgment which cannot be contradicted. Whatever may be considered the ground of Euclid's "axioms" so called, Euclid himself did not apply that name to them; but the first nine he called "common notions," and the last three (which are peculiar to geometry) he placed among the postulates (ἀποδείγματα), and heads them with "let it be granted." Now it is clear, from Newton's own words, that in calling his *Leges motus* "axioms," he does not imply that they are necessary judgments, but that he requires them first of all to be granted (however established) in order to the following reasoning. In other words, they are postulates, like Euclid's last three "axioms." In our modern use of the words "axiom," "axiomatic," there is always implied the ground why a proposition is demanded as granted, viz., because its necessity is self evident; but this wider use is not required by etymology, or (I think) in interpreting all ancient writings. F.M.S.

From *Nature*, 9, 462, April 16, 1874.

The problem of Soviet scientists: a reply to John Ziman

Professor Eric Burhop, of University College, London, replies in an open letter to points raised in an earlier article on relationships with Soviet scientists.

DEAR JOHN,

Although there may be many things wrong with the organisation of science and the attitude toward some scientists in the Soviet Union, I do not feel they warrant the kind of special action you propose in your article in *Nature* (246, 322; 1973).

In the first place your article is tendentious and contains a number of inferences which I believe you would have difficulty in establishing. It would indeed be a matter of concern if Soviet science "were to fall into decay and disrepute". Of course if, like Solzhenitsyn, we were to hark back a quarter of a century, there might be some cause for concern. But the Soviet scientific community has itself been able to correct the most glaring of the aberrations that gave rise to anxiety at that time. The difficulties it faces today, while no doubt often stupidly frustrating, are not of the kind likely to threaten Soviet science with "decay and disrepute". The reasons Soviet scientists often turn up late at conferences or do not turn up at all is mostly, though admittedly not entirely, due to a clumsy bureaucracy which affects not only scientists. These are the kinds of things—basically trivia, however maddening they may be—that can only be effectively dealt with by the Soviet scientists themselves. I agree that it would be beneficial if a greater number of Soviet scientists were able to come to conferences abroad. I think the position is improving but the problem is very largely one of foreign exchange of which there is a great shortage, affecting all travel. It would certainly be a more sensible use of the available foreign exchange to allow a larger amount for travel of scientists but this is not the kind of thing that can properly form the basis of anything approaching a demarche by the Royal Society.

Some criticisms you make are serious ones with which I would not disagree, but the situation is more complex than you imply. You ignore completely the differences in values characteristic of Western and Soviet society. For example, in Western society the increase of private wealth by speculation is regarded as normal, or even laudable. In Soviet society it is punishable very severely. In Western society too much concern for problems of peaceful coexistence, disarmament and the abolition of nuclear weapons is regarded as at best naïve and at worst subversive. In Soviet society these things are highly regarded.

In a society based on social ownership of the means of production, the operation of a planned economy is likely to require more restrictions in some directions than in a society based on the vagaries of the free market. Many people, including I believe many scientists or writers, may feel this a price well worth paying for a society founded on socialist principles, in which continued social, economic and cultural advance is assured. They may indeed assess these as far less onerous than the 'restrictions' inherent in inflation, unemployment and social insecurity which are unknown in their society but all too real in our own society.

Many of the disabilities to which you refer are related to the question of the emigration of scientists to Israel. The Soviet Union has consistently supported the Arab countries against Israel and this policy seems to have very wide support

among Soviet people who tend to regard those Soviet scientists who wish to emigrate at the present time and are presumably willing to help Israel in the war in somewhat the same light as British people on the whole regarded Oswald Mosley in 1939. It may be regrettable, but hardly surprising, that their colleagues have in some cases refused to work with scientists who have applied to emigrate to Israel. This is surely a passing phase and if and when a stable peace comes to the Middle East the campaign against the emigration of scientists to Israel will abate.

Arguing that the Council of the Royal Society should intervene, you say "such a statement would make it quite clear to the main body of Russian scientists that we understand their present position . . .", implying that they would welcome such a statement. I do not believe there is a basis for such a conclusion. I have come into contact with many Soviet scientists and I know that the vast majority would not welcome such intervention. Indeed this has been pointed out to me quite passionately by some eminent Soviet scientists who are by no means complacent about some of the aspects of the situation to which you refer. They feel that an intervention of the type you envisage would certainly make things worse by strengthening more 'hard line' as opposed to more 'liberal' tendencies.

The most important reason for opposing intervention is, however, surely the effect it could have on the development of scientific exchanges. You place very little store on these exchanges. Others, however, have had a different experience of them. The interests of both British and Soviet science require an extension, not a cutting off of such exchanges. There is, however, an even more important reason for fostering international scientific cooperation in general and cooperation between the Royal Society and the Soviet Academy of Sciences in particular. They are an important factor in building relations of friendship and understanding between our two peoples. They can assist in breaking down the fortress mentality which largely colours Soviet attitudes to the outside world. This attitude has been built up over the years as an understandable consequence of political attitudes towards the Soviet Union. It constitutes a major obstacle to the development of the easy, informal relations between Soviet colleagues and their opposite numbers in the West. I know you would like to see these relations develop and yet I fear that the kind of campaign you are sponsoring will have the effect of strengthening rather than loosening this fortress mentality.

For the Royal Society to intervene would represent a departure from long established policy. All through the Vietnam War it said not a word about the way in which modern scientific techniques were applied by the United States Army, assisted unfortunately, by many United States scientists who should have known better, in the development of defoliants, virus diseases of growing rice crops, riot control weapons, the electronic battlefield. In Chile at the present time the military junta has taken over the universities and many university staffs, including scientists, have lost their jobs, have been forced to emigrate, or even put in danger of their lives. Recent press reports make it clear that the United States Government continues its programme of 'behaviour modification' experiments on prisoners—a gross professional abuse of psychiatry, as you rightly say. I have not heard suggestions that the Royal Society should say anything about any of these things.

In my opinion, before the Council of the Royal Society starts making public statements about the matters you raise in your article it might appropriately look at things in Britain. I do not wish to exaggerate but, nevertheless, there are blemishes sufficiently serious for the National Council for Civil Liberties to feel impelled to set up a Council for Academic Freedom and Democracy here.

Yours sincerely,

ERIC BURHOP

international news

A CONTROVERSIAL scheme to explode a string of nuclear devices underneath the Colorado Rockies to extract vast deposits of natural gas has run into a critical snag. A key test of the technique, a 90-kiloton blast called Rio Blanco which was set off last year amid a storm of protest, has turned out to be something of a flop, and officials of the Atomic Energy Commission (AEC) are now trying to find out what went wrong.

The gas is trapped in small pockets in a layer of sandstone about a mile underground, and there is reckoned to be enough under the Rocky Mountains to supply the entire demand in the United States for about 10 years. But the sandstone is not porous enough to allow the gas to be extracted simply by drilling into it, and so the AEC together with an industrial partner, has been trying to free the trapped gas by smashing the rock with nuclear explosives.

The idea is to fire off a nuclear device in the gas-bearing sandstone, which creates a large underground cavern and fractures the surrounding rock for hundreds of feet in all directions. Gas then seeps into the cavern through the fractures and it is later pumped to the surface.

Rio Blanco was the third test of the technique, but it was the first to employ a radically new idea to improve the gas yield. Instead of firing off a single nuclear device, three explosives were placed in a vertical line, about 450 feet apart, and triggered simultaneously. The hope was that the caverns produced by each explosion would link up to form a huge cylindrical chimney in the sandstone layer, about 150 feet in diameter

Rio Blanco draws a blank

Colin Norman, Washington

and 1300 feet deep, surrounded by massive fractures radiating outwards.

But earlier this year, when the AEC began to extract gas from the chimney, it found that it was getting a yield only from the cavern created by the topmost explosion—somehow, the caverns either failed to link up or they had later become sealed off from each other.

Asked last week what went wrong, J. Keith Davey, an AEC official concerned with the project, said that several things could have happened. The simplest explanation is that the explosives were placed too far apart so that the caverns they created just didn't join up, but another possibility is that the chimney could have become blocked.

It is possible that the glassy melt formed by the intense heat of the nuclear explosions didn't fall to the bottom of the chimney, but blocked off the connection between the caverns. Another likelihood is that the rocks simply shifted after the explosions as Davey points out, underground mechanics at that depth are not well understood. Still another possibility is that the chimney could have been disturbed when the borehole was sunk into it to pump the gas to the surface, a suggestion which is given some credence by

the fact that about 12,000 barrels of lubricating mud were lost during the reentry operation.

Later this year an attempt may be made to sink an oblique shaft into the second cavern to try to provide some answers, but whatever went wrong the failure has greatly damaged the chances that nuclear gas stimulation—as the technique is called—will ever be turned into a commercial venture. The scheme has already run headlong in spirited opposition from several diverse groups, and technical problems at this stage could well send it to an early grave.

Rio Blanco itself was entirely an experimental test, but what is worrying opponents of nuclear stimulation is the prospect of a full-fledged commercial venture. To exploit the gas field under the Colorado Rockies entirely would require several thousand nuclear blasts, a prospect which pleases neither the people living in the area nor the oil companies who are hoping to produce oil from the shale fields which happen to sit immediately above the gas-bearing sandstone.

A repeat of the Rio Blanco test would be sure to attract a huge amount of opposition, particularly in view of the fact that two oil companies have just paid nearly \$210 million for the right to set up a prototype oil shale process on a small strip of federal land not far from the Rio Blanco test site. Alternatively, the AEC would be hard put to justify moving to a pilot scale nuclear stimulation operation on the basis of the Rio Blanco results. The failure is thus a critical blow to the whole enterprise.

Cash on the rail

Rail from Ascension Island, drawn by the explorer, Peter Mundy, 1656

WHEN does specimen collection of rare birds and animals for scientific study become unacceptable? This question has been exercising ornithologists on both sides of the Atlantic recently. The trouble seems to arise when enthusiastic ornithologists and museum staff visit remote places and offer cash and other inducements to the natives for rare birds dead or alive.

The most recently reported case concerned a member of the American National Museum of Natural History of the Smithsonian Institution, who, during a visit to St Helena for the admirable purpose of studying the fossil remains of flightless rails, admitted offering cash rewards after the natives re-

ported the presence of a living bird of this type. No specimen was in fact forthcoming and the author says that he is convinced that the bird was imaginary. But he might remember Charles Kingsley: "no one has the right to say that no water babies exist, till they have seen no water babies existing; which is quite a different thing, mind, from not seeing water babies".

Elsewhere in his article, the author says that the flightless birds of these remote islands were certainly only made extinct after men arrived. The Smithsonian seems to be following the Victorian idea that an animal is not discovered until it is safely stuffed in a museum.

Around the Solar system in 1,800 days

FOLLOWING the complete success of Pioneer 10, NASA has decided to re-target Pioneer 11, now en route for Jupiter, rather than simply to duplicate the earlier mission. As a result, Pioneer 11 will now swing by Jupiter, using that planet's gravity to assist it into a new orbit and a rendezvous with Saturn late in 1979. And that will pave the way for the planned Mariner missions to Jupiter and Saturn, which include the possibility of putting at least one of the Mariner craft in orbit about Saturn.

Pioneer 11 has now passed the asteroid belt and is more than 4.5 astronomical units (AU) from the Earth; its new path should take it to an encounter with Jupiter on December 2 or 3 this year. The latest Pioneer will pass much closer to the cloud tops of Jupiter than its predecessor (27,000 miles as against 81,000 miles, according to a report in *Aviation Week & Space Technology*, 100, 18; March 25, 1974). This close approach is essential if good use is to be made of the slingshot effect of Jupiter's gravity and using such approach can only be contemplated in the light of the Pioneer 10 data. Those data showed the structure of magnetosphere and radiation belts sufficiently clearly that the Pioneer project scientists are confident that Pioneer 11's new path will take it through a gap in those belts, so that in spite of its close approach to Jupiter it will receive less damaging radiation (by some 75%) than did Pioneer 10.

But the actual path followed by Pioneer 11 after the Jupiter encounter is almost as interesting as the objective itself. Like the recent Mariner 10 Venus/Mercury mission, which was the first to utilise a gravity-assisted trajectory, Pioneer 11 will actually be slowed down by its encounter with the first planet it passes (Jupiter). The new path will take the Pioneer across the leading edge of the planet (Pioneer 10 passed the trailing edge and was accelerated above escape velocity for the Solar System) and in a loop back

across the Solar System, to meet Saturn, eventually, on the opposite side of the Sun from the Jupiter encounter.

The slow journey back across the Solar System will take nearly five years, with Saturn being reached some time in October 1979. The closest approach to the Sun will be some 3.5 AU but the space probe will not have to face the hazard of the asteroid belt again, since its new path will take it out of the ecliptic plane. Clearly, this will provide a wealth of information about interplanetary space. But what are the prospects for the Saturn encounter itself?

Saturn orbits some 9.5 AU from the Sun, at which distance radio signals take 1.5 h to reach Earth. It would be asking too much to expect spectacular information to be relayed by the first probe to visit Saturn—but as long as the radio transmitter is still functioning useful data could be obtained simply by flying Pioneer 11 through the rings of Saturn to see if it hits anything. That would at least indicate the limits of safe orbits for the following Mariner craft.

It looks as if that at least should be possible, and some scientific information may also be gleaned as a bonus. The spacecraft's nuclear isotope generators were designed to produce 100 W five years after launch (April 1978 in the case of Pioneer 11) but judging from the experience gained by Pioneer 10 the generators are likely to last rather longer than anticipated. It seems feasible that all the experiments could still be operating in October 1979, with sufficient power available to relay their findings; and perhaps even pictures, over Pioneer 11's 10-W transmitter.

FOOTNOTE: It seems that the *Sunday Mirror* has even more faith in the versatility of NASA spacecraft and the power of the gravity-assist technique than NASA project scientists themselves. In the March 31 edition of that newspaper we were presented with a Mariner 10 picture of Mercury with a caption which ended "Mariner 10 is now hurtling through space ready to take pictures of Saturn, the ringed planet . . . in 1979".

Mars Sampler in 1981?

NASA engineers and scientists will be meeting in Washington on May 23 and 24 to discuss the feasibility of a unmanned Mars sampling mission. Such a mission could be flown as early as 1981 if there is cooperation between Soviet and American space agencies.

The prospect of complete collaboration between the two giants has been growing for some time, and the Mars project seems a logical next step. The mission divides clearly into two parts; one country could take responsibility for the launch from Earth and delivery to Mars of the sampler package while the other looked after that package and produced the means of getting the sample home.

Some of the possibilities which will be trashed out in detail in May are mentioned in *Aviation Week & Space Technology* (100, 14, April 1, 1974); support for the proposal is likely to be strong both because of the desire to develop from the 1975 Viking lander (assuming that is successful) and because the returned package need only be placed in Earth orbit, where it could be collected by the shuttle. But options are being kept open on such projects as Viking 1979 (*Nature*, 248, 15; 1974), and it remains to be seen whether the Russians would accept the proposal of a joint mission to bring back Mars samples.

Ring of little confidence

John Gribbin

SHOULD the Science Research Council (SRC) support the building of an electron storage ring at Daresbury to provide a central synchrotron facility when the electron accelerator NINA closes down in 1978? Taking advantage of a spare afternoon at the end of a conference on synchrotron radiation held at the University of Reading under the auspices of the Institute of Physics, the SRC case study and plans for such a facility were put to the physics community on April 2. Because of a clash of dates with a Chemical Society meeting, the proposal has still to be discussed with rank and file chemists. But the Reading meeting showed clearly that at the very least the proposal needs careful rethinking and emphasised the value of such discussions with the people who would be using such machines.

As at present conceived, the new machine would cost some £2 million to

build, with running costs in the vicinity of £750,000 a year. For this money, the facility would provide the first such source in Britain dedicated to synchrotron work—present synchrotron users at Daresbury and elsewhere are very much aware of their status as 'parasites' on the high energy machines.

Ten beam lines, each capable of supporting two projects, would eventually be available but it would take some 10 years to work up to this fully operational capacity. The machine would operate at 2 GeV with an electron current of 1 A, the planned radius of the electron orbit being 15 m, the bending radius of the magnets 5.55 m, the magnetic flux 1.2 T (12,000 gauss) and the total radiated power 240 kW. All that is impressive enough, as is the list of possible experiments which could be carried out with such a facility. But is it the best way to spend the available money?

Many of the physicists present at Reading expressed doubts about this. The most crucial question, which is not yet answerable, is just when the facility could begin operations. Both for economic reasons and because of the community which has built up around Daresbury, the plan envisages that the new ring would be built inside the NINA hall. Inevitably, that means that there must be a delay between NINA closing down and the new machine becoming operational. The optimists suggested, in the SRC plan, that the delay might be a year or so, provided work begins on the project soon. But few, if any, of the synchrotron users believed this. B. Bleaney (University of Oxford) went so far as to say that he would bet on a gap of more like four or five years in which British synchrotron workers would have no major facility in this country; there were no takers prepared to accept his bet.

That raises the question of just how useful such a machine will be in the mid-1980s. Certainly everyone present at Reading would have been delighted to have such a facility now but fears were expressed that European and American machines now being planned and built might have tackled the most exciting problems before the new British machine got a look in. Of course, such machines will be extremely useful for the foreseeable future, just as conventional X-ray sources, for example, have not been rendered obsolete by synchrotron facilities. But it is one thing to build such a costly installation, do the exciting work and then continue using it into a productive middle age, and quite a different kettle of fish to build an expensive facility knowing that it will probably only ever be used for routine, if valuable, work.

There was also some confusion about just how much the costs would be, in terms of experiments using the facility.

It was put to the SRC representatives that although their plan did not spell out the financing in those terms, a generous interpretation of the running costs, together with the proposal that ten "new projects" might start up each year, meant that each project had to be "worth" £100,000. That is a lot of project—something like three or four times the cost of typical projects being run in universities in the areas of research expected to benefit from the new facility. Even allowing for Parkinson's laws, is it really sensible to plan for such growth?

But there are two points to be considered against this apparently large expenditure. First, if only 100 people are using the machine, then its running cost of £750,000 a year breaks down as £7,500 a person a year—more the sort of figure which the average person can understand and, it seems, not a sum to make the SRC blanch. Second, at present, experiments funded by the SRC in universities have invisible means of support—they do not have to pay for buildings, for electricity, for non-scientific staff to keep the buildings running and so on ("heat, light and sound", as a wag in the audience put it). And in the present economic climate it is best, perhaps for the SRC to be seen to stand on its own two feet.

This problem, although slightly out of the mainstream of the Reading meet-

ing, is an interesting and tricky one. For, if the SRC grasps the nettle firmly and says publicly that its expenditure plans are based on the assumption of less university support, such bodies as the University Grants Committee will surely take note and reduce their allocations accordingly. On the other hand, if the SRC assumes continued support of this kind at present levels then it will be severely embarrassed if such support is not forthcoming.

It is certainly good to see the SRC encouraging open discussion at the early stages of planning such projects as the new storage ring and it was clear that both the SRC and the physicists were able to learn about each others' difficulties and needs at Reading. The plan as originally envisaged seems unlikely to survive and a powerful case can be made for pressing ahead more vigorously with such a project, perhaps at a different site, if there is to be such a ring at all. It also remains to be seen how the need for such a large sum might inhibit other activities by the SRC's Physics Committee—it is not difficult to think of ways of spending £2 million which would be at least as useful as building a synchrotron facility. But certainly there is less chance of ending up with an underused white elephant when the committee is taking such a receptive attitude to frank comments from the physics community.

Business report *Roger Woodham*

A HEALTHY increase in capital has been announced by Imperial Chemical Industries (ICI), following the publication of its annual report for 1973. The amount sanctioned is £250 million, 60% of it earmarked for the United Kingdom where the major project started in 1974 may well be a giant ethylene plant on Teesside producing 500,000 tons a year. This was originally to have been a three-way affair—Shell, ICI and BP—but Shell has now withdrawn for undisclosed reasons and a firm agreement has not yet been made between ICI and BP. Will intercompany squabbles spoil the attempts to avoid a recurrence of the plant overcapacity problems of recent years?

If all goes according to plan ICI will be livening up its investment in spite of Mr Healey's Budget. Just how things have ground almost to a halt recently is highlighted by figures in the 1973 report for fixed assets—plant, equipment, buildings and so on, the stuff of investment. In 1973 fixed assets increased from £1,160 million to just £1,185 million. By contrast, in 1964, 1965 and 1966 the assets in use were increasing by leaps and bounds, from £646 million to £760 million to £880 million.

The report also reveals some interest-

ing trends in ICI's sales, worth £2,166 million last year. Whereas in 1963 the United Kingdom accounted for 52% of the sales, in 1973 the proportion was down to 43%. Allowing for imports of raw materials and so on, ICI contributed positively to the British balance of payments by some £220 million.

●HELICOPTERS landing on oil rigs, and possibly ships entering estuary ports, may benefit in a few years from the improvements that continue to be made at the Mullard Research Laboratories, Redhill to its Microwave Aircraft Digital Guidance Equipment (MADGE). The basic system has NATO's blessing and is being manufactured commercially.

A substantial proportion of one of MRL's four divisions, which between them spend £3 million a year, is engaged on work of broadly this kind, sophisticated radar. The beauty of MADGE is that the stationary part of the system, which is 'interrogated' by a microwave signal from an aircraft (or ship) can be set up in only 15 minutes or so. Ideal, as NATO evidently thinks, for landing and takeoff near the front line, but also a good bet for civil aviation.

LATE LAST year, when Arab countries suddenly shut off oil supplies to the United States, the Nixon Administration and the United States Congress reacted predictably by espousing a pell-mell drive to make the United States independent of foreign suppliers of energy so that the country would not get caught short again. President Nixon dubbed the effort "Project Independence", and optimistically said that the goal of self-sufficiency could be reached by 1980—a prediction which he continues to make even though his own officials have publicly stated that it is totally unrealistic.

A striking aspect of the debate about Project Independence is that it has centred almost entirely on the levels of funding that have been proposed and on the way the project should be managed, but few people have publicly challenged the philosophy behind the enterprise. Like God, motherhood and apple pie, energy self-sufficiency is tacitly assumed to be good for America. But a report published last week by the Ford Foundation may change all that.

A preliminary publication designed to stimulate debate about the energy policy choices that now confront the United States government, the report says that the decision "to rapidly develop all federal energy resources simultaneously . . . may make sense in some areas, but as an across-the-board proposition it represents a failure to weigh conflicting values". For one thing, it may result in unacceptable environmental degradation, and for another, it may have damaging repercussions on United States foreign policy. Moreover, the report points out that Middle East oil can be produced at very low cost, and although at present prices it may seem economic to extract oil from shale and coal, there is no guarantee that these products would not be undersold by Arab oil in an open market.

Prepared by the Ford Foundation's Energy Policy Project—a \$4 million study which should be completed later this year—the report is an attempt to suggest that the United States is not "bound in an energy straitjacket" but has a number of policy choices available, ranging from a gradual progression to zero energy growth on the one hand, to aggressive development of new energy resources, so that Americans can continue to increase their consumption of energy virtually unchecked, on the other, the report outlines some of the social consequences of the options.

If the United States continues to increase its energy consumption at the same rate as in the golden years preceding the crisis—about 3.4% a year—production will have to be doubled by the year 2000. According to results of a study carried out by Resources for the Future, Inc., such a target could be met by an aggressive programme of

developing domestic sources of energy, including oil from the outer continental shelf, nuclear technology and shale oil. There is, however, some question about the availability of fossil fuels much beyond the year 2000 if they are exploited at maximum capacity for the next 30 years, and the energy demand could only be met by abandoning some environmental standards.

At the other extreme, the United States could move gradually towards

Ford spells out the energy choices

Colin Norman, Washington

zero energy growth by developing more efficient ways of using energy and by cutting back on consumption. If such a path is followed, it would mean some rather fundamental changes in the American way of life, but the report suggests that the goal could be met without dire consequences, either to individuals directly or to the economy of the United States. In fact, the report states that "because of its greater efficiency in using energy, the [zero energy growth] scenario would include many more energy benefits than the nation now enjoys".

A key to this optimistic prediction is an orderly progression to zero growth, rather than a sudden dislocation, so that the goal will be reached towards the late 1980s. By that time, individual energy consumption would have risen by about 10% from the present level. "Managing a transition to zero energy growth appears to be possible if the change takes place gradually over ten to twenty years as part of long term planning and a growing social consensus as to its desirability", the report states.

To achieve the goal of zero growth changes must be made—for example people would have to spend less time travelling, efficient rapid rail links would have to be developed between cities, there would have to be a trend toward multi-family housing, the growth of energy-intensive industries would have to be slowed down, there would have to be more recycling of valuable products such as aluminium and the use of plastics would have to be curtailed. Clearly, such changes will not come easily and will demand a fundamental change in governmental thinking to ensure that an orderly transition is made to "a society that husbands its resources, including energy".

Between those two extremes lies the possibility for increasing energy production while reducing the growth in demand. This scenario is called the "technological fix scenario" in the report and in a free enterprise economy it is probably the most likely course for the country to follow. To illustrate the choices available, if such a path is followed, the report outlines some of the decisions which will have to be made to cut the rate of growth of energy consumption to half that pertaining before the energy crisis began to bite.

One fundamental fact to emerge is that although some research and development will be required to develop technologies for conserving energy—such as solar heating and cooling, and heat pumps for residential heating—"the major uncertainties are political, institutional and economic questions rather than physical or technical limitations". Which is a little like saying that the United States could move from a capitalist to a socialist economy but for political constraints.

Another important aspect of the technological fix scenario is that with an aggressive programme of energy conservation, choices can be made between competing technologies for energy supply. For example, the report points out that if strip mining of coal in the western United States is considered to be too destructive to the environment, other sources of energy could be expanded to fill the gap.

Alternatively, the report mentions in several places that fundamental questions have arisen in the United States about the safety and environmental risks associated with nuclear power, and it suggests that a moratorium could be called on the building of new power plants until such issues are resolved. Since the United States Atomic Energy Commission (AEC) is basing its case for the fast breeder reactor chiefly on the fact that it will supply a huge proportion of the country's energy requirements by the end of the century, the AEC will not take very kindly to the suggestion that the entire nuclear programme could be abandoned without plunging the United States into total darkness.

The fact that such options exist has largely been closed over in the debate about Project Independence, and the chief result of the report will be to strengthen the hand of environmental groups in their opposition to some of the more damaging energy projects. But this document is simply a discussion device, and the facts behind the analysis will not be published until late this year. In particular, the final report will present a more closely argued analysis of the consequences of a transition to zero energy growth.

Professor R. V. Jones. A wartime picture by Larry Burrows

Concurrence in learning and arms

David Davies

It was the reunion of the Class of '45 at a recent meeting of the Royal Society to discuss the effects of two world wars on the organisation and development of British science. No gathering of reminiscing fighter pilots could match this occasion, where the boffins, with their H2s, operations research, radar and the Manhattan project, assembled once more to draw the morals, not in a smoky bar room but in the clinical jumbo jet interior of Carlton House Terrace. Two Lords, two Members of the Order of Merit, seven knights and all Fellows of the Royal Society, except the educator, the historian and the industrialist. The high-spot seems to have been the night before when the speakers gathered round the dinner table to swap stories—not, one of the participants pointedly told me, the sort of stories to be repeated within earshot of the Editor of *Nature*. Nevertheless there was sufficient vigour left on the day to delight an audience of two hundred.

Before the twentieth century war had practically no impact on science, nor science on war. R. V. Jones (who had convened the meeting) named the few exceptions—Bacon had advocated "concurrence in learning and arms", Babage and Playfair, the extraordinary precursors of so much, had concerned themselves with science in warfare and Kelvin and Rayleigh advised the services. Organised science was still small; the Cavendish was getting by on £1,500 a year just before the First World

War (WWI), including demonstrators' salaries. There were terrible shocks to British complacency in WWI—gas, Zeppelins and U-boats were three scientific and technological tools of war which had to be countered. Science was also badly hit by the loss of Moseley and Hopkinson. Scientists were wasting their talents as cannon fodder and in the Second World War (WWII) a register of scientists was maintained.

The successes of WWII, particularly radar, finally ensured that science was moved closer to policy making. Lindemann was the first scientist since Playfair to be involved at governmental level and the need to share scientific results led to the dispatch of A. V. Hill, Ashby and Needham to Washington, Moscow and Chungking.

It is easy to see the importance of WWII because many of the participants are still around but WWI had an equally profound effect on science, as D. S. L. Cardwell pointed out. Germany had encouraged science-based industry and Britain's dependence on Germany in such matters as dyes, pharmaceuticals, instruments, fine chemicals and so on led to grave shortages. New ventures were launched—British Dyestuffs, research associations for industry and the Department of Scientific and Industrial Research (DSIR)—and by the end of the war the importance of science in education was realised. British science got a leg up from WWI but science in general lost much of its supranational character.

What sort of leg up did science get from WWII? This question occupied speakers for the rest of the day. The Second World War, it seems, gave a boost to scientists rather than science. For science itself there were obvious

gains such as nuclear physics, but also less obvious losses (C. H. Waddington held that without WWII molecular biology would be fifteen years older, Bernal and Astbury, not Watson and Crick being the midwives). In technology too there were both gains and losses, as D. S. Davies (ICI) detailed in a thoughtful paper. Prewar inventions such as titanium technology, jet engines and radar were clearly advanced but against this were setbacks in television, synthetic fibres and plastics. A static gross domestic product inhibited investment in special plant in the war, of course. Of specifically wartime inventions, maybe operational research was the only one which has so far had a major impact on Britain.

The effect on the scientists had, however, been colossal, both in the way they went about their science and in the way they ensured that government took note of them. J. A. Ratcliffe and Sir Edward Bullard told broadly similar stories. The scientist who in 1939 left a laboratory used to making do with no phone and no secretary, used to the idea that science was gentlemanly, cheap and simple and used to being rebuked by the chief assistant for using expensive wood to make breadboards ("mahogany, Mr Ratcliffe?") came back a changed man. He had learnt how to get his way, how to coordinate a team and how to use communications. The outward sign of this was the growth in numbers of research workers and the even more spectacular growth of the cost of research projects. As for biology, even though, as J. W. S. Pringle put it, this was not a biologist's war it changed the thinking of many who found pure research not so important and the possibility of doing new things and playing a role in public affairs attractive.

It was inevitable that American science should have come in for mention. Before WWII, said Lord Bowden, America had been regarded as subordinate to Europe in science but the vision of men such as Vannevar Bush and a willingness to buy scientists, if necessary, swung the pendulum. Besides, nuclear energy, the first big science, was growing and, as Sir Harrie Massey described, the Manhattan project sowed the seeds for a whole new approach to scientific operations in which the United States had a clear start. The Second World War had given many scientists a sense that what was possible in principle was also possible in practice. In wartime, of course, this did not have to be profit making; the carrying over of this attitude into peacetime has not necessarily led to the science-based industries hoped for.

R. V. Jones considered government establishments in a second paper. The aim before WWII had been to keep

government and university scientists close together, but after WWII, despite early hopes that teaching and fundamental research could have priority over defence research, the government gained at the expense of the universities.

In 1931 there were 1,053 civil service scientists. By 1961 there were 15,474. Jones was critical of the trend and contrasted it with the United States, where nongovernmental laboratories had been fostered in the 1940s. Overenthusiastic claims for the Comet plane, thermonuclear fusion, the Einstein redshift in the Mössbauer effect and carbon fibres had not helped the reputation of the

establishments. In wartime they flourished because of the spirit of collaboration. Not so in peacetime when the spirit was competitive.

Finally, how did scientific advice to the government change as a result of the war? Lord (*alias* Solly) Zuckerman sketched the transition from the advice, often informal, of the thirties, of Lindemann, Tizard, Blackett, Bernal, and so on, through the war when many scientists became planners with operational research and a few were involved in the determination of national policy, to the post war period with the greatly enhanced reputation of the scientist in government. Science advisers were

brought in all over the place but their utility was restricted as they were rarely allowed to be more than technical assistants, kept out of the bigger issues of government. This trend culminated in the creation of a Chief Scientific Adviser in 1964, though if there were an issue on which he and trade union leaders had something to say, the trade unionists could be expected to carry more weight.

A fascinating meeting. Too bad the youngsters chose to stay in their laboratories. Those with scant regard for the history of science as a proper study (and there are many) would have been won over by this delightful occasion.

correspondence

Nuclear simplicity

SIR—The paramount command for nuclear power reactors is safety. The next most important requisite is the lowest possible cost of the electric power actually supplied to the grid.

Safety depends directly on simplicity and so does the cost of safety. An inherently simple plant can be made safe more easily and at a lesser cost. Simplicity also favours high availability and thus a lower unit cost of electrical power.

Simplicity is rare because new ideas are rare. The original safety containment concept was based on countering the hazard of brute force by brute strength until, quite late on, somebody hit on the idea of providing a condensational pool. The same is true of the coolant recirculation pumps: first external pumps with large connecting pipes, then external pumps with internal jets and small pipes, then axial internal pumps without any pipes. Pipes may fracture. In both cases the simpler and, with hindsight, very obvious concept resulted in lower costs and much greater safety.

I owe the concept of ponnery to my children who used to build edifices of chairs, saucepans, the cat's basket, vacuum cleaner and so on, up to the ceiling, one 'pon the other. Such an edifice is called a ponnery. I now classify nuclear reactors into 'naturals' and ponneries.

The naturals are simple and obvious. I know of only two: the boiling water reactor (BWR) and the gas-cooled fast breeder (GFB). The pressurised water reactor (PWR), the heavy water reactor (HWR) and the sodium-cooled fast breeder (SFB) are ponneries.

The BWR works on a direct cycle.

Disadvantage: active live steam. The main activity (^{16}N , generated by activation of oxygen) is, however, so short-lived that only the head end of the turbine need be shielded. Advantages: inherent, very rapid reactivity control (voids ratio), so that load follow-up is automatic and power excursions are self-limiting. No primary/secondary heat exchangers, so, no unnecessary thermodynamic losses and no leaky tubes, therefore high availability.

The PWR is, by comparison, a ponnery. It has a complex primary cycle, huge primary/secondary heat exchangers (very expensive and very leak-prone) and a low thermodynamic efficiency factor. High primary pressure (expensive), very modest live steam pressure (inefficient). From the nuclear point of view, sluggish reactivity control, hence the need for boron poisoning, hence a further sprouting of the ponnery to take the boron out again. It is inherent in a ponnery that the more you try to improve it the more profusely it sprouts.

The HWR introduces yet a third compartment, leaks from which must be controlled particularly carefully because heavy water is expensive. This is a ponnery within a ponnery. Its only advantage is the use of natural uranium. Once European enrichment facilities become available, this issue will be dead.

The obvious successor to the BWR is the fast breeder. But which one? The SFB is an obvious loser. It is of necessity a three-cycle system. Sodium is not a natural answer for transferring heat to water.

The natural winner seems to be the GFB, especially at high temperatures (process heat) and in combination with helium turbines (direct cycle, high effi-

ciency, minimum waste heat dumping problems). The technological problems associated with high temperatures (950°C and more) are worth solving, in contrast to those of the SFB. In its prime, perhaps 10 years from now, the direct cycle GFB should prove even simpler than the BWR.

Yours faithfully,

news and views

When did plate tectonic processes begin?

A POINT often underemphasised by earth scientists, presumably because they think it too obvious to mention, is that their view of the Earth's behaviour is still heavily biased by data relating to the comparatively recent past. That the bias exists is, always has been, and probably always will be, inevitable, if only because younger rocks are generally the more abundant, the less altered from their original states and the more easily associated with processes whose occurrence is beyond doubt. But there are dangers in it nevertheless. For one thing, the more biased the results towards a relatively restricted range of time, the greater is the inclination to succumb to an uncritical belief in some uniformitarian world view and all that implies in terms of extrapolating the present into the past. It is perhaps significant that as geologists have become more familiar with the pre-Mesozoic and even the pre-Palaeozoic they have become less concerned to defend uniformitarianism or actualism (between which nine out of ten earth scientists cannot tell the difference anyway) and more confused about what these terms really mean or ever meant (except in terms of a reaction against biblical catastrophism). As a result, 'uniformitarianism' has now come to represent little more than a vague attitude, a negative thought that whatever uniformitarianism is it is not catastrophism. On the other hand, so strong is the historical influence that what may seem to be no more than an outmoded philosophical idea may still have deep-rooted behavioural repercussions.

The attempt to extend plate tectonic concepts further and further into the past is a good case in point. The widely-accepted group of ideas known collectively as the new global tectonics is based on data which relate to only the past few hundred million years, or less than 5% of the Earth's history; yet these concepts have succeeded in converting most earth scientists from a belief in a static Earth to a conviction that the planet is on a state of more or less continuous mobility. But however impressive and conclusive the evidence, such a radical transformation is the world view based on such a small proportion of the Earth's existence inevitably raises the question of what is the Earth's 'normal' long-term behaviour. Is the present and very recent mobility of the Earth typical of much or most of the planet's existence, or is it a very late development? Or to put the question in the way it is more usually posed: are plate tectonic concepts applicable to pre-Mesozoic time or not? It is a question every bit as, if not more, fundamental than that raised by Wegener at the beginning of this century.

It is in the nature of things that it should also be a difficult question to answer. What can be said immediately is that if plate tectonics is taken to imply the relative motions of land masses, the extension of the concept to the pre-Mesozoic is inherently implausible. The breakup of the ancient supercontinent of Pangaea some 200 million years or so ago is now well established, and the subsequent motions of the resulting continents have been charted by palaeomagnetic and other means. Finding the physical mechanism for the breakup and subsequent drifting is, of

course, a more difficult matter; but causes apart, the basic idea of continental dispersal from a single land mass poses no severe conceptual problems. By contrast, the proposition that Pangaea itself formed by the amalgamation of many land masses (presumably different in shape and number from the present continents) is conceptually altogether more difficult to accept, and the mechanism for such a union is unimaginable. It would be as easy to accept as, for example, the suggestion that meteorites may accrete in an environment comparable to that in which they disintegrate. That two, or even several, continents may collide and coalesce is not beyond the bounds of comprehension, but that all pre-existing land masses should combine into one can hardly be envisaged. Yet this is precisely what is envisaged by many who have sought to substantiate pre-Mesozoic plate tectonics.

It is at this stage that the dangers of a too uncritical acceptance of some basically uniformitarian viewpoint readily become apparent. It is worth pointing out, for example, that the close association between continental drift (that is, the relative movement of land masses) and plate tectonics at the present time does not necessarily imply that pre-Mesozoic plate tectonic processes would involve drift. In a system of plates in which only the plate containing Pangaea was continental, Pangaea could move relative to the poles as a single land mass; and proof of no relative motion between Pangaea's component masses would not necessarily disprove the existence of plates. This would avoid the problem of the inherent unlikelihood of all land masses coalescing; and the fundamental mobility of the Earth during the pre-Mesozoic need not be rejected.

On the other hand, it must be admitted that the supporters of pre-Mesozoic plate tectonics have often come to that view not directly through a simplistic uniformitarianism requiring the permanence of continental drift, but through an altogether different, though perhaps equally simplistic, uniformitarianism involving pre-Mesozoic drift as a precondition. Specifically, they have argued that modern orogenic belts are the direct result of plate interactions, that the characteristics of ancient orogenic belts are similar to those of more recent ones, and therefore that ancient orogenic belts are the result of ancient plate interactions—in particular the suturing of previously distinct crustal plates which have converged. Africa, for example, contains a pattern of stable cratonic blocks with intervening orogenic belts ranging in age from more than 3,000 million years to Palaeozoic. The argument here then is that the orogenic belts were formed at plate margins, the plates being the cratons which drifted together from positions thousands of kilometres apart.

But although the evidence for this view seems quite strong and is well supported by data from other parts of the world, most notably North America, there is also convincing support for the older, alternative model in which the cratons have remained essentially stationary relative to each other and the orogenic deformation developed between them. There is also a great deal of evidence which at various times has been taken to favour both the stationary and drifting craton models. The fact is that the available data are conflicting; and it seems unlikely that the question will ever be resolved on geological grounds alone. On the other hand, such are the pressures to interpret the past in terms of the present, and such is the strength of the new global tectonic hypotheses, that the case for pre-Mesozoic plate

tectonics has often contrived to appear overwhelming. As recently as last year, for example, McElhinny (*Palaeomagnetism and Plate Tectonics*, Cambridge University Press, 1973) could conclude that it "now seems likely that the processes of plate tectonics have been a feature of all geological time" while at the same time admitting the paucity of palaeomagnetic data from the Precambrian.

That this conclusion may be premature was recently brought home sharply by Piper *et al.* (*Nature*, **245**, 244; 1973) who argued that, whereas the geological evidence may be inconclusive, "palaeomagnetic evidence is potentially decisive". They then concluded from the available palaeomagnetic data that the principal cratonic areas of Africa were probably in roughly their present relative positions as early as 2,200 million years ago and thus that the adjacent orogenies were probably ensialic. More generally, they were able to suggest that the concentration of all existing land masses in one large continent during the late Precambrian remains a serious possibility.

Later in this issue of *Nature*, McElhinny *et al.* present new palaeomagnetic data from Australia and India; and although their interpretation of these and the older data differs from that given by Piper *et al.*, they nevertheless reach the same general conclusions. It thus begins to look more and more as though the inherently implausible never happened. On the other hand, it must be stressed that even now pre-Mesozoic, and especially Precambrian, palaeomagnetic data are still far too sparse to enable any conclusion from them to have the degree of certainty attributed to comparable conclusions relating to the past 200 million years. But what is now certain is that only palaeomagnetism will be able to resolve the issue one way or the other.

P.J.S.

Origin of asteroids

BETWEEN the orbits of the planets Mars and Jupiter resides a collection of minor bodies known as asteroids. They were first discovered in 1801 by the Italian monk Guiseppe Piazzi and caused considerable excitement because their mean solar distance of 2.8 astronomical units fitted neatly into the Titius-Bode series of planetary distances. More than 3,000 have now been discovered and it is estimated that ten times that number may well be susceptible to photographic detection. They are all small, Ceres the largest being about 770 km across, and having a mass of about one five thousandth that of the Earth. In fact the total mass of the asteroids is estimated to be only twice that of Ceres. They also seem to be highly irregular structures, their internal gravitational force being much too weak to make them spherical.

Where do these asteroids come from? Three theories are presently in fashion, the oldest, first propounded by Olbers more than 150 years ago, has the asteroids originating from the cataclysmic disruption of a planet which had an orbit between those of Mars and Jupiter. This received a new lease of life when Ovenden (*Nature*, **239**, 508; 1972), on the basis of his principle of least interaction action, found that he could explain the present planetary positions if another planet ninety times heavier than Earth disappeared between Mars and Jupiter some 16 million years ago.

A second theory (Kuiper, *Astron. J.*, **55**, 164; 1950) produces asteroids by the collisional fragmentation of a small number of planetesimals, these planetesimals being the primaeval condensates from the solar nebula, the fundamental building blocks of the Solar System. The present Hirayama families of asteroids with similar orbital elements are supposedly produced by the fragmentation of individual planetesimals.

Theory three (Alfvén, *Icarus*, **3**, 52 and 57; 1964) has the asteroids accreting by random aggregation. As the bodies are inelastic, collisions tend to reduce relative velocities and thus to equalise orbits. The particles always return to the point in space of their last collision leading to collisional focusing and the production of a stream of particles of very similar orbits and low relative velocities—an ideal situation for accretion. If this theory is correct the asteroids are in the process of growing into a planet with a mass similar to that of Mercury.

Napier and Dodd (Royal Observatory, Edinburgh) in a recent edition of the *Monthly Notices of the Royal Astronomical Society* (**166**, 469; 1974) have tried to discriminate between these theories by considering the observed mass distribution of the asteroids, the observed rotation periods and also the physical tenability of the processes required.

The number-mass distribution of asteroids smaller than 20 km obeys a power law where dN , the number with masses between m and $m + dm$, is given by $dN \propto m^{-8} dm$. Dohnanyi analysing the data obtained from the Palomar-Leiden survey of asteroids finds them to have an s value of 1.84; Hellyer found $s = 1.77 \pm 0.05$ using the same data. Napier and Dodd calculate a theoretical value for s by using a Monte Carlo simulation technique to look at random collisions between particles. Now collisions can cause erosion or fragmentation depending on the size of the incident particle. The authors find that erosion is negligible, a rocky asteroid typically only losing 8% of its mass before it suffers fragmentation. The collision fragments have an s value of between 1.5 and 2.0, the s value increasing with collision energy.

Starting with a sample of 7,400 bodies of differing mass and an s of 1.80, these authors found that 500 random collisions did not change s at all but that after this number the s value slowly increased reaching about 1.90 after 800 collisions. The larger bodies would not obey the power law because they were not being replenished. Napier and Dodd tried a second theoretical model where bodies of the same mass were allowed to collide and coalesce on collision. Independent of whether the accreted particles are replaced s quickly reaches a value of 1.5. These findings indicate that observed asteroidal s values can be produced by fragmentation and also by planetary disruption but not by accretion, thus removing one theory of origin.

Asteroids have rotation periods of around 8 h which for the larger ones is close to the limit for rotation-induced fission. Napier and Dodd find that the observed spin periods can be produced by fragmentation as there is abundant collisional energy available whereas accretion would give unobservably long periods. Fragments from a disrupted planet, however, would have rotation periods similar to that of the planet, which could quite easily have been in the region 8 to 10 h. So once again accretion is ruled out but the other two theories are tenable.

The authors have pointed out (*Nature* **242**, 250; 1973) that Ovenden's hypothetical planet cannot have been disrupted by the release of chemical or nuclear energy or by tidal instability induced by Jupiter. Disruption could be caused by detonation but chemical detonation is of too low an energy while nuclear fission detonation requires the sudden creation of a large supercritical mass within the planet. Another possibility is that the solid planetary mantle constrained a high pressure core until breaking point was reached; however, the tensile strength of rock is such that a planet of mass greater than 4×10^{23} g would not disperse the fragments to infinity and it would be impossible to lose the 99.9% of Ovenden's planet to leave just the asteroids remaining.

So only the planetoid hypothesis is left. This is consistent with meteorite geology which shows evidence of a cooling phase and shock processes which could have occurred at fragmentation. It is temporally reasonable as collision

dynamics indicate that Ceres would collide with one of the 30 asteroids capable of fragmenting it every 10^{10} yr indicating that the large asteroids are original planetesimals. More-

over, the dispersion of fragments after collision can produce orbits of reasonable inclination to the ecliptic just like those of the asteroids.

Cell movements in *Hydra*

CELL movement is a fundamental component of morphogenesis. Cells may move as three-dimensional masses, in sheets or as individuals. The movements must be controlled by signals available to the cells, and the signals may be involved in the control of development in general. One can therefore deduce much about developmental control from observing cell movements; for example, melanocyte migration in amphibians is under chemotactic control, as is the aggregation of slime mold amoebae.

In *Hydra*, Wolpert has shown that much morphogenesis is possible by a combination of cell movement and differentiation without any increase in cell number. Herlands and Bode (see *Nature*, **248**, 387; 1974) have now published observations on nematocyte migration, which confirm the general model for the control of *Hydra* development put forward by Wolpert and his collaborators.

Nematocytes are stinging cells used for the capture and paralysis of prey. They arise by differentiation from interstitial cells in *Hydra*'s body column, and migrate into the tentacles where they position themselves in the ectoderm. Although there are at least four types of nematocyte, Herlands and Bode examined the two commonest, desmonemes and stenoteles.

The authors grafted the upper halves of *Hydra* labelled with ^3H -thymidine to unlabelled lower halves, and also made the reverse grafts. They examined the originally unlabelled halves for labelled nematocytes. Nematocyte migration was strongly biased apically; indeed, basal migration only occurred towards buds. There was no migration into the peduncle.

As there was thus already a clear suggestion of apical

preference in nematocyte migration, the authors tried further grafting experiments to determine whether the signal was produced by the head or was some underlying property of the cells through which the nematocytes migrate. The authors labelled gastric regions of *H. attenuata* with ^3H -proline and grafted unlabelled heads to either the basal or apical ends. They then measured the rate of accumulation of labelled nematocytes in the unlabelled, grafted heads. They found that stenoteles accumulate at the same rate in basal and apical heads, but that desmonemes, for the first 3 days after grafting, accumulate in apical heads at a greater rate. After 3 days there was an increasing rate of migration by desmonemes into basal heads. These times correlate well with the times for polarity reversal by basally grafted heads found by earlier workers.

This interpretation was checked by grafting a head to the basal end and a peduncle to the apical end of a labelled gastric region. The addition of a peduncle is known to accelerate polarity reversal, and indeed there was no indication that the desmonemes migrated according to the original tissue polarity. Stenoteles, as before, migrated to the head regardless of polarity.

These results show that two kinds of signal are used—both an underlying property of the tissue, which may correspond to Wolpert's "positional value" and which can determine polarity, and a signal emanating from the head independent of polarity. This might be a chemotactic signal. The signals closely correspond to those already invoked for models of the control of *Hydra* development.

An SV40 that doesn't help adenovirus

THE inability of human adenoviruses to undergo a productive cycle of growth in simian cells—possibly because of the failure of a late function—can be overcome by coinfection with simian virus 40 (SV40). Adenovirus T-antigen (Feldman *et al.*, *J. Bact.*, **91**, 813; 1966; Malmgren *et al.*, *ibid.*, 262) and viral DNA are produced (Reich *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **55**, 336; 1966; Baum *et al.*, *Virology*, **34**, 373; 1966), whereas the production of some late protein is inhibited in monkey cells (Friedman *et al.*, *J. Virol.*, **5**, 586; 1970; Henry *et al.*, *Nature new Biol.*, **233**, 39; 1971). The region of SV40 DNA that specifies its helper function was located in an adeno-SV40-nondefective hybrid by Lewis and his colleagues (*Proc. natn. Acad. Sci. U.S.A.*, **63**, 1128; *J. Virol.*, **11**, 655; 1971). These workers selected, from adenovirus populations that had been grown in the presence of SV40, mutants that were able to grow productively on monkey cells without the assistance of exogenous SV40 virus.

Some of these mutants contained segments of SV40 DNA covalently linked to adenovirus DNA sequences. In these adeno-SV40 hybrids, the region of the adenovirus substituted for by the SV40 sequences does not seem to be essential for adenovirus growth. The substitutions of SV40 sequences all begin at the same place in the adenovirus genome (14% from one end) but in different mutants the SV40 sequences can range in amount from 11–43% of the SV40 genome, the smallest being 17% of the genome (see *J. Virol.*, **12**, 643; 1973). All these SV40 sequences start from one place on the SV40 physical map which is 0.11 map units to one side of the *EcoR*₁ cleavage site (see *J. Virol.*, **12**, 653;

1973). The exact nature of the SV40 helper function is not known but it has been mapped in a region of the genome that is thought to specify early functions.

Jerkofsky and Rapp tested the enhancing ability of some temperature sensitive mutants of SV40. Both late mutants, which did synthesise viral DNA, and an early mutant, *tsA7*, which did not synthesise viral DNA, but did induce host DNA synthesis (*J. Virol.*, **8**, 516; 1971), were able to enhance the production of adenovirus at the nonpermissive temperature in monkey cells. These results support their idea (*Virology*, **51**, 466; 1973) that an early function of SV40, possibly related to the induction of host DNA synthesis, is involved.

Kimura, in this issue of *Nature*, has tested the helping ability of temperature sensitive mutants of three complementation groups defined by Kimura and Dulbecco (*Virology*, **52**, 529; 1973). He also finds that late mutants will enhance adenovirus growth at the nonpermissive temperature. The early mutant *ts640* was unable to facilitate adenovirus growth at the nonpermissive temperature although enhancement was normal at the permissive temperature. This mutant *ts640*, like *tsA7*, is temperature sensitive for the production of viral DNA. It is not known whether *ts640* induces host DNA synthesis; it may differ in this respect and thus represent a second class of early mutants of SV40 (possibly a fourth complementation group). A further characterisation of *ts640* should be accomplished soon.

Kimura has mapped his genetic marker in the SV40 helper function: it occurs between 0.11 and 0.28 map units on the SV40 physical map.

Wasa's cannon balls saved from corrosion

ON August 10, 1628 the Swedish warship *Wasa* started on her maiden voyage out of Stockholm harbour. She sank within minutes. 333 years later she was raised and is now a magnificent tourist attraction. She is also, to Mr L. Barkman of the Statens Sjöhistoriska Museum in Stockholm, "an enormous corrosion experiment". Barkman, along with Dr O. Arrhenius and Mr E. Sjöstrand report on the problems of preventing further rusting away of iron from *Wasa* in a recent publication of the Korrosionsinstitutet in Stockholm (*Conservation of Old Rusty Iron Objects*, Bulletin 61E, 1973; SKr 16.00).

Even at the time of the *Wasa* mishap the water in Stockholm harbour was fairly noxious. Dumping of rubbish had probably ensured that there was little or no dissolved oxygen present. The water was saline and at a temperature of around 3° C. Into this murky environment dropped a thousand iron objects such as guns, 24-pound cannon balls, chain shot and pike shot. Thousands of nails and one-inch diameter bolts also went down, but of these only two fragments remain. The guns were at first held down in their carriages, but were soon salvaged by the primitive means available in the seventeenth century. Presumably the forgings rusted rapidly—today there is practically no sign of them on the 64 gun carriages and 52 gun ports. The environment is still hostile. New one-inch diameter iron bolts were used during the salvage operation, and after a year the diameter of the worst affected had been reduced to one third of its original value.

While forgings such as nails, bolts and gun fittings disintegrated, cast iron objects fared much better; not that the corrosion was any the less, but castings (cannon balls, for instance) have retained their structure. This is believed to be an effect of the higher carbon (3½%) and silicon (1%) content of the cast-iron balls. Analyses of the rusty outer layer of a typical sample showed that the percentage of carbon and silicon in the corroded material was up to 12% and 5% respectively, whereas iron was down to 43%. Nearly all the iron was in oxides, but there was about 1% chlorine, mostly from chlorides formed in salty water. In a limited-oxygen environment the final product of the oxidation process would be Fe_3O_4 , black magnetite.

The rusted outer layer of cannon balls was on average 1.4 cm thick; this implies a lower corrosion rate than for the bolts, but the majority of balls were protected by mud. It is clear that in the corroded layer many of the iron compounds have been dissolved away but a

total collapse of the fabric of the rusted layer has probably been averted by the enriched carbon and silicon fraction.

The dissolved iron compounds did not get far, as there were no currents. When *Wasa* was raised it was a rich mixture of colours, from mud mixed with precipitated oxides and salts. Stalactites of iron oxides, silicates and sulphates hung from the decks. The much admired black oak colour of the hull was the result of impregnation with several tons of iron.

A very serious problem arose the moment the iron objects came out of the water. Oxidation continued—now in an oxygen-rich environment so the end product is Fe_2O_3 , red haematite, but more damaging was the chloride activity. In moist air, FeCl_2 and FeCl_3 go through a cyclic process, precipitating iron hydroxide. The pitting that this

causes is the most dangerous threat to iron that has been in seawater, and the threat cannot be arrested by standard cleaning and drying processes. Corrosion in the atmosphere would have rapidly destroyed the museum exhibits. Dramatic evidence of this was already present in Stockholm. A cannon from a seventeenth century wreck had been salvaged in 1953, scraped, brushed, treated with antirust oil and exhibited. The photographs show its decline in 18 years.

Within a month the *Wasa* specimens were visibly corroding further; one cannon-ball fell apart. Unlike most corrosion problems in which the aim is to clear the surface of rust, in this case it was necessary to halt the chemical processes but keep the structure intact. To do this the Stockholm workers decided to attempt to reduce the oxides and

Cannon from the Riksäpplet which foundered in 1676: left, after salvaging in 1953; right, the same with severe corrosion damage in 1972.

chlorides to the metallic form. Hartwich had first done this in the 1880s with small rusty samples at 500 °C in a hydrogen atmosphere; the process is widely used in industry, but not in museums.

A cylinder of depth 126 cm, radius 23 cm was loaded with the samples (for instance six cannon balls) which were then placed in a furnace in hydrogen. Reduction was carried out at 600 to 800 °C and after a period of about a day the process was complete—not only were oxides absent but chlorides too had been reduced to iron. Chemical analyses show that there was generally no trace of chlorine and all the iron was in the metallic form. Subsequent coating with an antirust agent and accelerated rusting tests show that the objects are now fully protected against corrosion. They now sit in the Wasa Museum—uncorroding and with the right shape.

Success of super labs at Cologne meeting

from a Correspondent

THE Spring meeting of the Cologne Institute of Genetics (February 22-24) opened with a symposium on tumour viruses which, as W. Doerfler (Cologne Institute of Genetics)—who organised it—pointed out, really dealt with DNA viruses, since even the RNA viruses discussed by P. Vogt (University of Southern California) and J. Dahlberg (University of Wisconsin) have a transitional DNA phase.

Transcriptional maps of the adenovirus genome in productive infection are emerging both from the Wallenberg Laboratory at Uppsala and from Cold Spring Harbor. L. Philipson (Wallenberg Laboratory) described the techniques used by his group to obtain adenovirus DNA fragments from cleavage with restriction enzyme and labelled either in the heavy or the light chain. The amount of labelled DNA could be measured after the templates had been hybridised with excess unlabelled RNA, to give the quantity of DNA transcribed from either the light or the heavy strand of the restriction enzyme fragments.

Philipson's results proved entirely compatible with those of the Cold Spring Harbor group, presented at the symposium by W. Keller. The highlights of Keller's talk were the description of a new approach to sequencing viral DNA using a series of restriction enzyme cleavages which should greatly facilitate what is normally a long and painful process, and the results of the analyses of six hamster cell lines transformed with adenoviruses.

All the transformed lines seem to

hand, at least a portion of restriction fragment F located near the middle of the DNA towards the C fragment end was absent from all the lines. Keller speculated that the adenovirus DNA was integrated into the host chromosomes and that the functions contained in the retained portion of fragment A were necessary for its maintenance.

A. Lewis (National Institutes of Health), in a thorough analysis of the non-defective adenovirus-SV40 hybrids, described the unequivocal mapping by heteroduplex analyses of the order of several early SV40 functions. The question whether viral DNA becomes integrated into 'transformed' lymphocytes was raised by T. Lindahl (Karolinska Institute), who showed that the link between Epstein-Barr virus DNA to lymphoblast DNA was not stable in alkali, although a substantial portion of the viral DNA banded in caesium chloride with host DNA. Only when the DNA was sheared into small fragments were the host and viral DNA sequences effectively separated by isopycnic banding.

Vogt effectively summarised the work on RNA tumour viruses with a lucid exposition of the dilemmas with which analyses of the structure of oncornavirus are fraught. Most of the data, including those on the kinetic complexity of the genome, suggest that it is haploid and segmented. But reservations on this conclusion must remain because all of the RNA segments, and not just one, decrease in size on the mutation of sarcoma viruses to become defective or leukaemogenic.

The symposium concluded with a *tour de force*: the announcement of the sequence of the transfer RNA molecule which serves as the primer for DNA synthesised on the 70S RNA template by reverse transcriptase. This was the fruit of a collaborative project involving Dahlberg at Madison (who presented the paper) and M. Bishop's laboratory at the University of California in San Francisco, and it illustrated one of the most conspicuous incidental points brought out by the meeting. This was the contrast in the accomplishments of the large institutionalised collaborative groups such as those at Uppsala, Cold Spring Harbor, NIH, and on the San Francisco-Madison axis, and those of the smaller laboratories, both European and American, represented at the meeting. It was the superlabs which, by approaching complex problems from several directions simultaneously, emerged as the more effective, despite the inevitable loss of scientific identity resulting from the dilution of credit among individual contributions.

have a portion of the terminal restriction fragment A and all but one contain at least a portion of the C fragment located at the other end. On the other

Perfusing the female reproductive system

from our
Steroid Biochemistry Correspondent

WITH the well known limitations of most *in vitro* techniques for studying the metabolism of tissues, the use of perfusion or superfusion techniques has become more popular. In the field of reproductive biology, interesting results have been obtained by perfusion of the human ovary, placenta or foeto-placental unit. Tojo *et al.* (*Amer. J. Obstet. Gynec.*, 118, 119-129; 1974) have now achieved *in vitro* perfusion of the human uterus and fallopian tubes as well as the ovary.

Before removing the utero-tubal-ovarian unit, the arterial pressure, pulse rate and blood flow were measured and the pressure wave form of the uterine arteries was recorded. The unit was connected to the perfusing machine through the bilateral uterine arteries and the bilateral uterine and ovarian veins and was perfused in such a way that the pulse rate and pressure of the input of the perfusate were similar to those expected in the uterine artery *in vivo*. This was achieved by using a Bellofram-type artificial heart driven by a liquid amplifier, a pressure wave form regulator for the perfusate, an oxygenator, organ chamber, suction pump for venous return and an autoregulatory thermocontrol mechanism.

The viability of the unit during perfusion was tested by measuring the erythrocyte count, haematocrit, pO_2 , pCO_2 and pH values and the haemoglobin, lactate and pyruvate content of the perfusate.

Tojo *et al.* obtained successful perfusions of three utero-tubal-ovarian units, one obtained during the menstrual period and two during the mid-luteal phase of women with normal ovarian function. Addition of human chorionic gonadotrophin (HCG) to the perfusate increased the progesterone secretion from the ovary obtained during the luteal phase but not from that obtained during menstruation. When tissues obtained at the thirteenth week of pregnancy were perfused, there was a rapid increase in the HCG content and a gradual increase in the content of human placental lactogen (HPL) of the perfusate. Active nucleic acid synthesis was shown to occur in the trophoblastic tissue.

These preliminary results suggest that the utero-tubal-ovarian unit maintains its viability for some considerable time when perfused. If this is confirmed in further investigations, application of this method should help in the elucidation of many problems of reproductive physiology and pathology.

Rethinking about the sarcoplasmic reticulum

from a Correspondent

COINCIDENTALLY independent groups in London, Toronto and Heidelberg, have published in three different journals results that clarify the disposition and functions of membrane proteins in the sarcoplasmic reticulum of rabbit skeletal muscle.

Major proteins

The sarcoplasmic reticulum is a membrane specialised for transport and binding of calcium in muscle tissue and, as it has few proteins, it presents considerable advantages for study of cation transport through membranes. The major protein is a Ca^{2+} -activated ATPase (molecular weight approximately 102,000-115,000) which is tightly integrated into the membrane and is only released by detergents. Several other acidic proteins can be removed more easily, by extraction with chelating agents for instance. Calsequestrin, a protein with the ability to bind large numbers (30-40 per mole) of calcium ions at rather low affinity in the presence of 0.1M KCl, was originally suggested by MacLennan to play a part in cation binding in the reticulum. Calsequestrin is a glycoprotein and contains about 1 mol. of sialic acid, clearly not enough to account for the total number of cation binding sites, most of which probably involve acidic amino acid residues of the protein.

Another acidic protein, with molecular weight 55,000, binds calcium ions with high affinity even at high ionic strength (0.1M KCl) but with low capacity (about 1 mol. per mol). The other acidic proteins bind calcium but with very low affinity at any ionic strength. There is, however, some genetic variability in the total number of high or moderately high affinity calcium binding proteins and certain rabbits contain a second calsequestrin that is slightly smaller, with molecular weight 44,000 (MacLennan, *J. biol. Chem.*, **249**, 980-984; 1974). The mutation in this membrane protein seems to be a deletion and loss of a peptide sequence rich in methionine and cysteine. The mutant sarcoplasmic reticulum seems to be more active in Ca^{2+} transport than normal sarcoplasmic reticulum and the Ca^{2+} binding ability of the mutant protein is not affected by the deletion.

Calsequestrin

Calsequestrin was believed originally to be located in the interior of the sarcoplasmic reticulum and to play a part in sequestering calcium transported to

the inside of the vesicle by the Ca^{2+} -activated ATPase. Thorley-Lawson and Green (*Eur. J. Biochem.*, **40**, 403-413; 1973) suggest, however, that calsequestrin may be at the exterior face of the sarcoplasmic reticulum membranes, in sites exposed to the aqueous environment. This is certainly a more likely location for an extrinsic protein such as calsequestrin, which can be largely removed from intact closed membrane systems by extraction with 1 mM EDTA. The material removed by the chelating agent is reversibly bound to depleted membranes in the presence of Ca^{2+} indicating a binding to the lipid bilayer mediated by cations, with Ca^{2+} perhaps involved in some interaction between the acidic calsequestrin protein and the polar head groups of phospholipids. Candidates for a function as an internal calcium store may therefore have to be looked for elsewhere; possibly the acid protein of molecular weight 55,000 fulfils this role.

Calcium-activated ATPase

A second revision of the original model proposed by MacLennan for membrane proteins in the sarcoplasmic reticulum concerns Ca^{2+} -activated ATPase. These molecules were thought to be entirely represented by the 7.5-9 nm diameter particles seen in the freeze fractured faces of the membrane, that is to say, placing the ATPase molecules within the hydrophobic interior of the membrane. The recent reinterpretation makes the more acceptable proposition that the particles revealed in freeze fractured preparations represent the hydrophobic 'tail' of the ATPase that is firmly integrated into the membrane interior. The density of intramembranous protein domains is similar to that found in human erythrocyte membranes and representing the hydrophobic 'tail' of the major glycoprotein. About half of the Ca^{2+} -activated ATPase molecule is exposed on the exterior surface of the lipid bilayer where it is available for reaction with trypsin or lactoperoxidase (Thorley-Lawson and Green, *loc. cit.*; Migala, Agostini and Hasselbach, *Z. Naturf.*, **28**, 178-182; 1973; Stewart and MacLennan, *J. biol. Chem.*, **249**, 985-993; 1974). Since the sarcoplasmic reticulum is impermeable to protein reagents, trypsin and lactoperoxidase will initially only modify proteins on the external surface of these microsomes.

Structural relationships

The ATPase forms projections which consist of a 4 nm knob on a 2 nm stalk extending outwards from the external face of sarcoplasmic reticulum and seen in negatively stained preparations.

Very similar projections are produced in vesicles formed artificially from purified ATPase by removal of detergent from solubilised preparations of the enzyme. The projections are destroyed by high concentrations of trypsin with loss of enzymatic activity. ATP (and sucrose) protects the loss to some extent. Thorley-Lawson and Green (1973) found that at lower levels of trypsin, ATPase is split into two pieces of very similar size (40,000 and 55,000) which remain attached to the membranes. The fragments of molecular weight 60,000 are degraded to yet smaller units of molecular weights 33,000 (that contains the phosphorylated site) and 24,000, and all of these are iodinated by lactoperoxidase added externally suggesting that they exist on the outer surface of the membrane. The fragment of molecular weight 60,000 thus represents the stalk of the ATPase and the 55,000 molecular weight fragment, which is not iodinated, is buried within the membrane, as expected for a hydrophobic 'tail' equivalent to particles of the size seen in the freeze fractured faces of the internal membrane. The internal particles and the non-iodinated fragments of molecular weight 55,000 persist within the membrane of extensively trypsinised preparations which is consistent with these being the part of the ATPase integrated into the membrane. Thorley-Lawson and Green found that this part of the enzyme molecule is not iodinated even when both faces of the membrane are accessible to labelling reagents. If the ATPase does span the width of the membrane therefore, and this is the simplest model to explain the Ca^{2+} transfer across the membrane, it does not expose any significant amounts of iodinated tyrosine nor trypsin sensitive bonds in the region.

The structural relationship of the intramembranous particles and Ca^{2+} -activated ATPase is also implied by their coordinate increase in the muscle microsomes during chick embryonic development. Two papers by Martonosi and his colleagues (*J. biol. Chem.*, **249**, 612-623 and 624-633; 1974) describe developmental changes in the sarcoplasmic reticulum of chick skeletal muscle. The increased transport of Ca^{2+} during embryonic and postnatal development is directly related to concentration of Ca^{2+} -activated ATPase in the membranes of the sarcoplasmic reticulum. There seems to be an inverse relationship during embryogenesis between the appearance of the Ca^{2+} -activated ATPase and a Ca^{2+} -insensitive Mg^{2+} -activated ATPase. This second enzyme appears early in development and subsequently declines. It would be interesting to know whether these ATPases are independently controlled. The alternative is to assume a precursor

function for the Mg^{2+} -activated enzyme which acquires calcium sensitivity at a relatively late stage in development, for example, by interaction with 'coupling factors' which link ATP hydrolysis to Ca^{2+} transport. The lack of a subunit structure for the Ca^{2+} -activated ATPase of rabbit sarcoplasmic reticulum tends to make this assumption less likely, although it is an intriguing possibility.

Solar wind blows gusty at sunspot maximum

by our Cosmology Correspondent

THE continuing story of the influence of the Sun on terrestrial events has developed a stage further with the report by Intriligator of observations which provide the first evidence for long term variations in the solar wind associated with changes in the solar cycle (*Astrophys. J. Lett.*, **188**, L23; 1974). Events such as weather variations and modulation of the Earth's spin rate associated with the solar cycle of activity are now becoming well documented, and in recent years it has been established that there is a solar modulation of cosmic rays which is in anti-phase with the solar cycle. All this evidence points to variations in the solar wind as, if not the root cause, then at least the next link in the causal chain. But since suitable space vehicles which can provide essentially continuous monitoring of the solar wind have only been available for some ten years—about the length of one solar cycle—it is hardly surprising that such solar wind variations have only now been directly confirmed.

Intriligator's work is concerned with variations in the solar wind which are the result of changes in the high speed stream structure. The data were obtained by Pioneer and Vela spacecraft; they show variations in the number and intensity of high speed proton streams, and the average solar wind speed, between 1965 and 1971. Early in the period studied a high solar

wind speed of 626 km s^{-1} was measured, on January 20, 1966, and in all five high speed streams (the slowest with velocity 497 km s^{-1}) were observed between December 25, 1965 and February 3, 1966. But this represented the low point of activity during the period of the investigation.

When longer stretches of data are examined, it turns out that there were more high speed streams in 1968 (44) than in any of the other years of the study; as Intriligator puts it, the solar wind is more "gusty" around the time of maximum solar activity. On 230 days in 1968 there was high speed streaming activity in the solar wind; at the other extreme, all but 73 days out of 270 studied in 1971 were free from gusts.

This immediately offers an explanation of the modulation of cosmic rays over the solar cycle. At solar maximum, there is a much greater chance that cosmic rays entering the Solar System will encounter high speed streams, and this produces more modulation of the cosmic rays. When the solar wind is calm, it is easier for cosmic rays to penetrate the solar wind and reach Earth. The yearly average of the solar wind speed itself varies over the solar cycle, and is highest at solar maximum; there seems little doubt that this is a real effect which provides an important insight into the workings of the Solar System.

Genome organisation in eukaryotes

from a Correspondent

ANALYSIS of the organisation of nucleotide sequences in DNA of the more highly evolved eukaryotes is proceeding rapidly at present and has revealed some intriguing but so far unexplained phenomena. Following up their initial observations on the formation of DNA rings and other circular structures (*J. molec. Biol.*, **51**, 621; 1970), Thomas and his associates in a series of papers (*ibid.*, **77**, 25-99; 1973) have estimated that as much as half the DNA in mammals, insects and amphibians is composed of tandemly repeated or intermittent tandemly repeated sequences clustered in groups which they call *g* regions. The number of *g* regions in three *Drosophila* species is about 5,000 which corresponds to the number of cytologically observable bands or chromomeres in their polytene chromosomes.

Similar measurements for the mouse and *Necturus*, which have respectively fifteen and seven hundred times more DNA than *Drosophila*, reveals that the number of *g* regions is about 40,000 and 1.5 million respectively. This probably means that the one to one correlation between *g* region and

chromomere number observed in *Drosophila* does not hold in other organisms since the chromomere number (lampbrush chromosome loops) in *Triturus* has been estimated at 4,000. These results have relevance for the problem of the very large differences in genome size between closely related organisms. Increased genome sizes seem to be based largely on increased numbers and only marginally on increased size of *g* regions, since the estimated sizes of *g* regions in mouse and *Necturus* are only twice that of *Drosophila*.

The kinds of experiments Thomas and his colleagues have done to reach these conclusions are the measurement of the frequency and contour length of rings and ringlike structures observed by electron microscopy in preparations of DNA renatured to low C_0t values after treatment with *Escherichia coli* exonuclease III, an enzyme which digests one strand of a DNA duplex from 3' to 5'. DNA molecules resected by this enzyme will have two single strand ends which if complementary will tend to renature to give rings and other ring-like structures. No rings are produced by treatment of bacterial DNA in the same way, though many phages may cyclise through the presence of so called sticky ends which may occur naturally as in λ or produced by exonuclease III treatment as in T7.

Thomas *et al.* have shown that the frequency of rings is linearly related to the extent of resection up to a maximum plateau level which is 300 nucleotides for mouse and *Drosophila* and 500 for *Necturus*. These figures are presumably related to the length of the repeating sequences involved. Providing rings are formed in optimal resection and renaturation conditions, the frequency of rings is primarily a function of DNA size and is maximum with DNA of 1-2 μm in length regardless of organism. Such rings have very good thermal stability suggesting that the region of overlap is of the order of 200 nucleotides with very little if any mismatching, since thermal stability under ionic conditions reflects both length and fidelity of hybrid duplex. This means that the minimum length of the repeat unit is 200 nucleotides and that they show very little divergence by base substitution.

Fewer rings are created both with larger and with smaller DNA molecules. The reduction with increasing length is interpreted to mean that related repeated sequences are clustered into regions which Thomas *et al.* call *g* regions. An alternative explanation for this observation—that longer fragments have a greater distance separating potentially reactive single strand ends resulting in slower renaturation kinetics—was eliminated by a study of the effect of fragment length on the rate of

Total number of days on which high speed "gusts" were observed in the solar wind. —, Smoothed sunspot numbers; —x—, measured sunspot numbers. Data for 1965 and 1971 are based on 136 and 270 days of data, respectively.

cyclisation. Similarly the reduction with small DNA molecules was not due to slower renaturation kinetics of small fragments resulting from their decreased flexibility. It is argued that reduced ring frequency with molecules less than 1-2 μ m is evidence for tandem repeats being spaced by non-repetitious sequences. Although Bick, Huang and Thomas (*J. molec. Biol.*, **77**, 75; 1973) tried to find evidence for the presence of this predicted non-repetitious DNA by examining rings prepared for electron microscopy in high concentrations of formamide, which would reveal unpaired single stranded regions within the terminal region of overlap, they were unable to do so. They concluded that either the non-repetitious sequences do not exist, which is unlikely, or they are too long or too short to be observed.

Similar conclusions concerning the interspersion of repetitive and non-repetitive sequences have been reached by other groups using different techniques. For instance, Davidson *et al.* (*J. molec. Biol.*, **77**, 1-23; 1973) used labelled *Xenopus* DNA sheared to various known lengths denatured and then renatured, in the presence of excess cold *Xenopus* DNA of 450 nucleotides length, to C_0t 50, at which point predominantly repetitive sequences have renatured. They found that as the length of labelled DNA increases so a greater amount is bound to hydroxyapatite. Hydroxyapatite binds double stranded but not single stranded DNA at low salt concentrations and therefore allows their separation. In the conditions of the experiment any non-repetitive sequences, although remaining single stranded, will bind to hydroxyapatite if they are covalently linked to renatured repetitive sequences.

The curve relating the proportion of 3H -labelled DNA fragments containing a repetitive element to fragment length shows three things. A steep linear increase (4% per 100 nucleotides) up to an inflexion point at about 700 nucleotides length and 60% fragments bound, followed by a slower linear increase (0.7% per 100 nucleotides) up to 4,000 nucleotides length and 80% fragments bound. The first part of the curve does not extrapolate through zero bound at zero length but through about 20% representing the amount of repetitive DNA in the genome. Davidson *et al.* interpret these data on the basis of a model in which 50% of the *Xenopus* genome consists of repetitive elements about 300 nucleotides long interspersed with non-repetitive sequences 700-900 nucleotides long. A further 25% consists of repetitive sequences interspersed with longer (>4,000 nucleotides) non-repetitive sequences. The remainder is composed of unique sequences (20%) without detectable repetitive elements and of tandem, low complexity repeti-

tive sequences (5%) without detectable non-repetitive elements. Similar experiments with sea urchin DNA (Graham *et al.*, *Cell*, **1**, 127; 1974) show that an identical model may be constructed. Furthermore, in two earlier papers (Kram *et al.*, *J. molec. Biol.*, **64**, 103; 1972; Wu *et al.*, *ibid.*, **64**, 211; 1972) on the organisation of repetitive sequences in *Drosophila* DNA other groups reached similar conclusions.

Although it seems likely on present evidence that a general model in which repeated sequences alternate with unique sequences in eukaryotic DNA can be constructed, a good deal more work is required to reveal in detail which repeating patterns are universal and to provide some notion of their relevance to genome function.

Pattern formation in insects

from our Insect Physiology Correspondent

THERE are two ways in which the differentiated pattern of the living body may be supposed to arise. Each group of cells forming a given element in the body pattern may be derived from one progenitor cell, so that each component of the pattern represents a clone of cells which continues to propagate a persisting state of determination. Or, the cells forming an element of the body pattern may not have a different ancestry, or 'lineage', from the surrounding cells: their characters may have been determined by their position in the body. It can, of course, be argued that the second alternative is merely a repetition later in development of the same process by which the initial clones of the former alternative came into existence.

In normal development it seems clear that both these modes are concerned in the final generation of pattern. Many years ago, Sturtevant utilised the tendency of certain strains of *Drosophila* to form sexual mosaics (as the result of a spontaneous elimination of an X chromosome from somatic cells during embryonic development) in order to demonstrate the stage of development at which this mutation occurs and to relate this with the mosaic pattern in the resulting adult. This was done by coupling the mosaic strain with bristle characters that could be observed in the cuticle surface, and using the results to study the derivation or 'cell lineage' of the surface of the adult fly. Sturtevant found that related cells remain adjacent in patches without intermingling; that the occasional loss of an X chromosome happens at the early cleavage divisions; and that the mosaic patches of the opposite sex represent clones of these mutant cells.

Recently there has been a renewal of

interest in this approach to the problem of differentiation. Garcia-Bellido *et al.* (*Nature new Biol.*, **245**, 251; 1973) used somatic crossing-over induced by X rays to generate marked clones in *Drosophila* in which he could follow the distribution of characters in the cuticle of the wing surface. The resultant wings were made up of mixed clones, some of marked cells homozygous for the wild type allele of minute, M^+/M^+ ; others, the unmarked cells of the heterozygous strain, M^+/M^- . The marked cells have a much higher growth rate than the unmarked heterozygote. But in spite of this they did not overgrow the unmarked cells. It turned out that the wing is subdivided into eight compartments, and, provided a clone is generated after the time of final subdivision, it is strictly confined to one compartment. But within this compartment the cells could be differentiated by local control so as to contribute to the ordinary wing surface, to parts of wing veins, or to marginal bristles—depending not on cell lineage but on position at the time of differentiation.

Lawrence (*J. Embryol. exp. Morph.*, **30**, 681; 1973) now describes experiments in this same general field carried out on the milkweed bug *Oncopeltus*. He deals solely with the integument of the abdomen. Mild X irradiation of the egg led to somatic mutations which resulted in changes in the pterin pigments of the epidermal cells from the normal orange to deep orange, transparent, white or pink. As in Sturtevant's experiments these mutations resulted in clonal patterns of epidermal cells which are readily recognised by their unusual pigmentation. The results provide much information about the timing of determination for the structure of the abdomen, the number of cells which furnish the ancestry for a single abdominal segment and so forth. Again it is evident that the clones are subject to strict control. If the ancestral cell mutates after segmentation of the presumptive abdomen has been determined (during blastoderm formation), the clones are restricted to a single quadrant of a segment (dorsal or ventral, left or right). The daughter cells forming the members of a clone tend to hold together in a clump, but they can mix with their neighbours and the groups become fractionated to some extent. On the other hand, they cannot cross the boundaries between segments, between dorsal and ventral, or across the midline of the body.

The effective boundaries between segments are established at the time, 10-24 h after egg laying, when the limiting membranes of the cells are developing in the blastoderm. The nature of these and other invisible boundaries between compartments will be a key question in the understanding of differentiation.

Palaeomagnetic results and late Precambrian glaciations

M. W. McElhinny, J. W. Giddings & B. J. J. Embleton

Research School of Earth Sciences, Australian National University, Canberra, ACT, Australia

A combined late Precambrian to early Palaeozoic polar wander path, which differs from that previously proposed for Africa and South America, is derived for Gondwanaland. It suggests that Gondwanaland existed at least 750 Myr ago. The widespread distribution of late Precambrian glaciations can be explained in terms of this polar migration. It is predicted that the late Precambrian and Cambrian part of the North American polar wander path may be more complicated than previously supposed.

PIPER *et al.*¹ have tested whether the concepts of modern plate tectonic theory, as applied to several Phanerozoic orogenic belts²⁻⁶, can be applied to all ancient orogenic belts. Their analysis shows that all palaeomagnetic pole positions for Africa between 2,200 Myr ago and about 450 Myr ago (close of the Ordovician) lie on a single apparent polar wander path, irrespective of cratonic region. This suggests that the major cratonic areas were approximately in their present relative positions and orientations as early as 2,200 Myr ago. The younger intervening orogenic belts did not, therefore, result from plate accretion and subduction processes during an episode of major ocean closure which culminated in a continent-continent collision^{7,8}. Rather, the data support the view that these belts formed *in situ*, the stable cratonic nuclei remaining in place while the intervening belts themselves were being reactivated^{9,10}. Present data cannot, however, preclude the possibility that the belts resulted from the successive opening and closing of small intercratonic oceans.

Comparing with American Precambrian data, Piper *et al.*¹ further suggest that South America and, until about 1,000 Myr ago, North America may have been joined to Africa, and the concentration of all continental crust in one large mass until that time remains as a possibility. A further consequence of their interpretation is that if any of the Precambrian glaciations which affected south-west, central and north-west Africa, and parts of South America, originated between 900 and about 650 Myr ago, then they were formed in low latitudes^{11,12}.

New results from late Precambrian and early Palaeozoic formations in Australia (ref. 13 and J. W. Giddings and B. J. J. Embleton, unpublished information) and India^{14,15} allow us to extend the comparisons of Piper *et al.*¹ to include the whole of Gondwanaland. Our results lead to a different interpretation of the late Precambrian to early Palaeozoic apparent polar wander path. A consequence of this is that late Precambrian glaciations are restricted to high latitudes, as may be expected. Our interpretation does not, however, affect the general conclusions of Piper *et al.*¹, but leads to some predictions concerning the apparent polar wander path for North America.

Gondwanic palaeomagnetism

Palaeozoic and Mesozoic palaeomagnetic results, when referred to the reconstruction of Smith and Hallam¹⁶, suggest

that a common apparent polar wander path can be applied to the supercontinent from some time in the early Palaeozoic until its break up in the Mesozoic¹⁷. Interpretation of the early Palaeozoic section of the path has been uncertain because the poles tend to form rather a loose group in the region off north-west Africa. Stratigraphic sequences have been studied in both northern Australia and the Amadeus Basin of central Australia^{13,18}. The studied strata range in age from Precambrian-Cambrian through to the Ordovician. In each of these unrelated sequences a very large polar shift of 50°-60° of arc is observed during the earliest Cambrian, and in the Amadeus Basin¹⁸ the total shift during the early-Palaeozoic is about 90°. Figure 1 compares the Australian results on the reconstruction of Gondwanaland, with the corresponding late Precambrian and early Palaeozoic path for Africa and South America¹. It can be seen that the two Cambrian sections of the curves do not agree, and in fact have polar shifts in opposite directions.

There are two possible explanations of this disagreement. First, is that the earliest Cambrian sections of the two paths could refer to separate plates which collided to form Gond-

FIG. 1 Late Precambrian to early Palaeozoic apparent polar wander path for Africa and South America suggested by Piper *et al.*¹ (stippled path), plotted against the reconstruction of Smith and Hallam¹⁶ with Africa in its present day position. The large Cambrian polar shift observed in two stratigraphic sequences in northern Australia (solid line) and central Australia (dashed line) are shown for comparison. The pole designations are as listed in Table 1. Note that the path of Piper *et al.* places Africa in equatorial latitudes during the latest Precambrian. The solid black line connecting the mean Silurian-Lower Carboniferous (S-Cl), Carboniferous (C), Permo-Carboniferous (P-C) and Mesozoic (M) poles is the common path for this time interval^{13,17}.

wanaland during the mid-Cambrian. The timing then corresponds to the peak of the 550 ± 100 Myr pan-African orogeny, which was not the result of plate convergence¹. It thus seems unlikely that any one of these orogenic belts, such as the Mozambique belt, represents the suture between an eastern and a western Gondwanaland. The alternative is that it may be possible to re-interpret the African and South American data to conform with the Australian results.

Pole path for Gondwanaland

Table 1 lists all the palaeomagnetic poles for the Gondwanic continents between about 1,000 Myr and about 450 Myr (close of the Ordovician).

All the palaeomagnetic poles of Table 1 have been analysed with respect to the reconstruction of Gondwanaland of Smith

and Hallam¹⁶, and are shown in Fig. 2. We have been able to interpret all the data to account for the Cambrian polar shift observed in the stratigraphic sequences in Australia. All the South American poles designated Cambrian by Thompson²⁰ now fall on the Cambrian section of our combined path. African poles younger than about 700 Myr, but pre-Ordovician, have very poor age control, with the single exception of the 630 ± 24 Myr Ntonya Ring Structure of Malawi. We have been able to incorporate these poles into our combined path by minor rearrangement of their sequence without violating the tolerances on their age control. Significantly, this places the Ntonya pole at a point on the path just before the Precambrian-Cambrian boundary, whereas in the African path proposed by Piper *et al.*¹ it was out of sequence and inferred to have a much younger age.

We have not drawn the path through the two late-

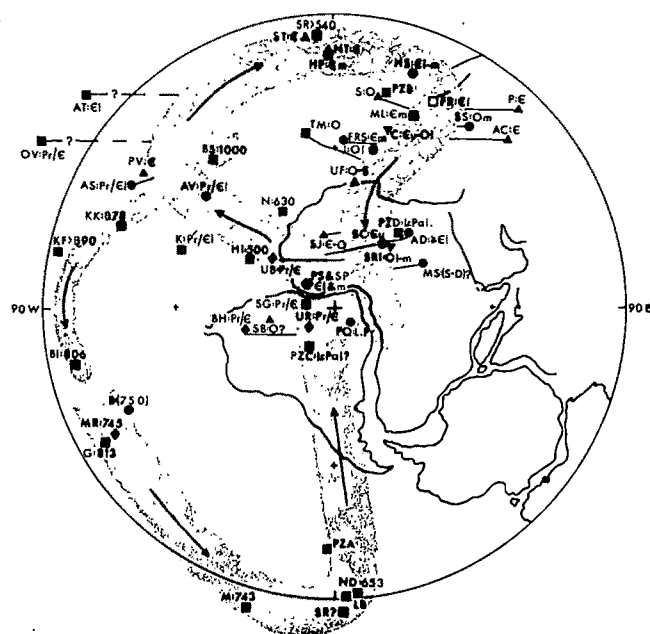

FIG. 2 Revised late Precambrian to early Palaeozoic polar wander path using all the Gondwanic poles listed in Table 1. Bearing in mind the uncertainties in some of the ages and the errors associated with the pole positions, all poles younger than 750–800 Myr are consistent with a common polar wander path when referred to the Smith–Hallam reconstruction¹⁶. The path is indicated by the broad band drawn through the poles. Before 750–800 Myr the sequence of poles is as yet only defined by African data indicated by the narrower band going back to about 1,000 Myr. ■, Africa; ▼, Antarctica; ●, Australia; ◆, India; ▲, S. America. Labelling as in Table 1.

Precambrian and early Cambrian Moroccan poles²¹ because this part of Africa might be a remnant of a Precambrian North America. It would not, however, be difficult to incorporate these into a slightly modified path, and then also identify a large Cambrian shift for North Africa to the pole for the Middle Cambrian Moroccan lavas. Latest Precambrian poles cluster in the region west or south of north-west Africa. The pole from the Cambro-Ordovician Hook Intrusives of Zambia is in this group but its circle of confidence is large enough for it to be associated with the later part of the curve in the region of the Sahara. The Cambrian poles from the Salt Range also seem to be out of sequence. This supports the suggestion of a separate Indus sub-plate¹⁶, but for an entirely different reason to that proposed. Originally the proximity of the Salt Range poles to those from the Bhandar and Rewa Series seemed to suggest that they were all of the same age¹⁴. A more likely late-Precambrian age for the Bhandar and Rewa Series now supposes that the structural setting of the Salt Range has caused their poles to be displaced from the Cambrian part of the curve. The pole from the Bolivian sediments of supposed Ordovician age falls in a region which suggests that these sediments may be rather older than supposed.

If the African part of the apparent polar wander path is to be extended back from the late Precambrian group it should continue southwards (Fig. 2) to the vicinity of the Mbozi Complex pole. It is at this point that our interpretation differs significantly from that of Piper *et al.*¹. The early Palaeozoic section of the pole path, as we have drawn it, represents the South Pole path (Fig. 2), but our interpretation obliges us to join up with what Piper *et al.*¹ regard as the North Pole path for about 700 Myr and older (Fig. 4 in ref. 1).

Unity of Gondwanaland

The 745 Myr Malani rhyolite pole for India plots close to a new Australian pole (J. W. Giddings, and A. R. Crawford, unpublished information) for which a provisional Rb–Sr age of 750 Myr has been estimated. These poles fall on the African curve near poles dated at around 800 Myr. This suggests to us that the consistency of the results for the Smith–Hallam reconstruction¹⁶ defines a single pole path extending back at least 750 Myr. It confirms the conclusion that the Pan-African orogenic belts must have been formed *in situ*¹. We can now extend the case of the intercratonic belts within Africa to those within Gondwanaland, such as the Mozambique belt and the eastern Ghats belt.

Late Precambrian glaciations

The occurrence of glacial deposits (tillites) in many late Precambrian formations throughout the world has led to the hypothesis that a widespread glaciation occurred just before Cambrian times^{22,23}. An essential point relating to this hypothesis is whether these glaciations occurred successively throughout polar migration or whether they occurred simultaneously and therefore perhaps extended to low latitudes. The interpretation of the late Precambrian to early Palaeozoic apparent polar wander path for Africa is crucial in this context because many of the late Precambrian glacial deposits are located in that continent. The pole path deduced by Piper¹¹ and Piper *et al.*¹ implies that the glaciated regions essentially occupied low latitudes, and that the glaciation was widespread¹². Our interpretation of the late-Precambrian to Cambrian pole path leads, however, to the conclusion that the pole migrated across South America (which was then joined to Africa) from south to north, during the late Precambrian. This is consistent with the occurrence of glacial deposits which are successively younger northwards along western Africa (Fig. 3).

In South West Africa two glacial episodes are recorded²⁴. Glacial horizons occur in the upper part of both the Damara

FIG. 3 The revised late Precambrian to early Palaeozoic apparent polar wander path for Gondwanaland compared with the distribution of glacial tillites. G.g. represent Ordovician and late Precambrian occurrences respectively. Glacial deposits in Africa possibly older than about 700 Myr and therefore not related to the drawn path have question marks. Successively younger late Precambrian occurrences along the west coast of Africa are matched by the south–north migration of the pole.

Fig. 4 Suggested revised North Pole apparent polar wander path for North America, which joins the Great Logan Loop³⁵ (1,200–1,020 Myr) to the Ordovician (O) part of the curve by means of a large Cambrian shift. Cambrian poles from: RB, the Ratchliffe–Brook formation¹⁸; WG, Wichita granites¹⁸; WB, Wilberns formation³⁹; LR, Lodore formation¹⁸; LF-I, 2A, 2B and E, Lamotte formation³⁸. Anchor points for the Great Logan Loop³⁵ are shown together with the Franklin pole³⁵ (F). Post-Cambrian Palaeozoic poles³⁹ are joined by a dashed line, the stars representing mean Devonian (D), Carboniferous (C) and Permian (P) poles.

and Nama Systems which are correlated with one another, and whose lower boundaries are not older than 650 Myr. Immediately underlying the Nama System are the Blaubecker Formation glacials and the Buschmannsklippe tillite. These are correlated with glacials of the Numees Formation which forms the upper part of the Gariep Group. A felsite lava in the Kapok Formation, which corresponds to the lower part of the Gariep Group, has an age of 720 Myr. The Blaubecker–Buschmannsklippe–Numees glacials are therefore very likely to be younger than 700 Myr. In Katanga the Petit Conglomerate is probably of glacial origin and has a minimum age of 620 Myr (ref. 25). The Grand Conglomerate of Zaire is, however, probably older than 850 Myr (ref. 25) and therefore relates to a very much earlier glacial episode. In north-western Africa the Saharan 'Eocambrian' tillite has been dated at 620–650 Myr (ref. 26), whereas, in Ghana the Oti tillite has an age of 620 Myr (ref. 29). This succession strongly suggests that the centres of glaciation followed the path of the pole in late Precambrian times as it swept from south to north, past southern, western and north-western Africa, between about 700 Myr ago and 620 Myr ago (Fig. 3). It seems significant that the best dated African late-Precambrian pole, the 630 ± 24 Myr Ntonya result, plots just off north-west Africa (Fig. 2) corresponding to the time when this region was extensively glaciated.

During the Cambrian the broad trends of climatic change are perceptible²⁸. In North Africa the occurrence of thick successions of Lower Cambrian warm water deposits include also archaeocyathid reefs. Cambrian rocks are frequently brightly coloured, indicating a warm climate, but they give way to more drab Ordovician sequences which culminate in the great, late Ordovician, Saharan glaciation²⁹. These broad trends are not only compatible with the Cambrian and Ordovician sections of the pole path, but also resolve a previously puzzling palaeoclimatic anomaly³⁰. From near polar conditions in north-west Africa the broad loop taken by the pole during the Cambrian placed North Africa in low latitudes, with a return to intermediate, and finally polar, latitudes during the Ordovician.

It is not clear how the pattern of late Precambrian glaciation in Australia fits into the polar migration proposed in Figs 2 and 3. Dunn *et al.*³¹ cite ages of 750 Myr for the Sturtian–Moonlight Valley glaciation, but these are all based upon Rb–Sr measurements on shales. The interpretation of isochrons drawn through such data in terms of age of deposition is very much an open question (W. Compston, personal communication), so that the relationship of these ages to

those on our pole path is unclear. We make the general observation, however, that between 750 Myr and 600 Myr a polar migration of at least 180° is proposed with respect to Gondwanaland. Very large polar shifts are observed in almost all continents during the late-Precambrian and Cambrian. It is therefore not surprising that the poles migrated quite rapidly over different parts of the globe leaving records of glaciated regions as they passed over the various continents. In these circumstances it is not necessary to invoke the hypothesis of an extensive synchronous world-wide glaciation that extended to low latitudes (see also ref. 32). The decisive test between the two hypotheses will come from palaeomagnetic measurements on the actual glacial horizons in various places around the world. If these measurements show that many of these deposits were formed in low latitudes then this will support the hypothesis of a synchronous world-wide glaciation.

Great Logan Loop of North America

There is an impressive correspondence between an extended loop in the African apparent polar wander path and the so-called Great Logan Loop³³ of the North American path^{1,11}. Both of these loops cover the time range 1,200–1,000 Myr. Our interpretation of the African polar wander path means that the poles in this time range are now south poles which can only be matched with the presumed North American north poles for the same time. The fit of the two loops is impressive, and so we tentatively suggest that the late Precambrian to early Palaeozoic section of the North American polar wander path may be much more complicated than previously supposed. Irving and Park³⁴ have already noted the very tentative nature of this section of the North American curve. There is only a single pole (the Franklin pole, 675 Myr) between the end of the Logan loop at about 1,000 Myr, and the Cambrian. During the same period in Africa the polar shift was more than 180° (Fig. 2). During the Cambrian alone the pole shift was about 90° . Furthermore, Cambrian results from the Bohemian massif have previously been interpreted in terms of a large polar shift of about 130° (ref. 35) and a large polar shift is also recorded in the Cambrian of Siberia³⁷.

The Lamotte formation of Missouri (Cambrian in age, although the fossil evidence is poor) shows four distinct palaeomagnetic poles³⁸. Poles from the higher horizons are in two groups (2A and 2B), related to their stratigraphical positions, and suggest a polar migration during the Late(?) Cambrian. Poles from the lower horizons seem to be anomalous. No reason is apparent for group 1 and the other (Locality E) is close to the Carboniferous pole for North America. Carboniferous remagnetisation has been proposed, although no evidence has been given either to suggest how this arose or why it occurred selectively at only one locality. Studies of the Ordovician Trenton Limestone³⁷ have shown that the hypothesis of widespread late-Palaeozoic remagnetisation of Lower Palaeozoic rocks is no longer tenable. We therefore interpret these poles as representing a polar migration during the Cambrian.

Figure 4 shows how it is possible to join the later Palaeozoic poles for North America through an extended Cambrian path, to the opposite poles of the Logan Loop. These poles become the north pole path for North America with the consequence that the plot of the Logan Loop in the Pacific^{33,34} represents the south pole path. It is then readily matched with the African loop (see ref. 1). Our prediction therefore is that extensive studies of late Precambrian and Cambrian rocks of North America (1,000–500 Myr) will reveal a complicated apparent polar wander path with a polar shift through at least 180° .

We thank Drs J. C. Briden and J. D. A. Piper for providing us with a preprint of their analysis of African palaeo-

magnetic data and for their stimulating and friendly discussion of our disagreements with some of their interpretation. We also thank Drs A. R. Crawford and W. Compston for providing us with a preliminary Rb-Sr age for the Precambrian B group dykes of Western Australia (Table 1).

Chimaera mouse study shows absence of disease in genetically dystrophic muscle

Alan C. Peterson

Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada

Chimaeras have been derived from aggregation of normal and dystrophic mouse embryos which had healthy muscles of almost totally dystrophic genotype, and diseased muscles of normal genotype. These results suggest that extramuscular factors must be implicated in muscular dystrophy.

UNTIL recently muscular dystrophy in man and animals was considered to result from a genetically determined primary defect within the muscle fibres themselves. Evidence is now accumulating which suggests that dystrophic individuals have an abnormality within the nervous system which may itself be largely responsible for the muscular disorder; namely, an abnormal trophic influence of the motor neurones on the affected muscles^{1,2}.

One ideal situation which could allow the investigation of the site of the primary genetic lesion would be an adult animal in which either genetically dystrophic muscle was innervated by a normal nervous system or genetically normal muscle was innervated by a dystrophic nervous system. The mouse chimaera offers an opportunity to approach this ideal situation without requiring that the animal undergo surgical manipulations, with subsequent establishment of regenerative processes³.

Mouse chimaeras are derived from the aggregation of pre-implantation embryos (each of eight cells) of differing

genotypes. These mosaic morula are cultured for 24 h (in which time they differentiate to single blastocysts) and are then transferred to the uterus of pseudopregnant females to complete development⁴. The chimaeras of interest here would derive from aggregation of dystrophic and normal embryo types. It was hoped that the resulting *in vivo* situation would make possible the study of the interaction between genetically defined muscle and the rest of the organism during development, and in the mature state.

In these chimaeras, if muscles of identified dystrophic genotype were found to have normal characteristics it would be unlikely that the disease could be due to a primary myopathy. In addition, if genetically normal muscle showed dystrophic characteristics, then this too would support the inference that there was an extramuscular component of the disease. Conversely, a direct correlation between dystrophic genotype and dystrophic characteristics would support the original myogenic hypothesis.

The principal requirement was to have an adequate genetic marker with which to determine the muscle genotype. Amongst the inbred strains of mice there are several suitable markers, and for this experiment the electrophoretic isozymes of malic enzyme⁵ were incorporated as the genotype marker, for the mature muscles of the dystrophic-normal chimaeras.

An important feature of the proposed *in vivo* preparation is that the muscle would be investigated at a time when, in the lifespan of an animal with the dystrophic genotype, the

FIG. 1 Activity ratio of *Mod-I* isozymes in the heterozygote pattern from muscle supernatant. Correction factors were applied to densitometer results of chimaera muscle before calculation of relative *Mod-I^a/Mod-I^b* nuclei.

disease would be clearly shown⁶. The slow clinical progression of the disease in dystrophic mice with the new *dy²³* allele allows these mice to mate⁶, and homozygous dystrophic morula were obtained by direct mating of dystrophic pairs. For the experiment seven chimaeras of dystrophic \longleftrightarrow normal (C57Bl/6J *dy²³/dy²³* \longleftrightarrow SWV) and two of normal \longleftrightarrow normal (C57Bl \longleftrightarrow SWV) composition, all of which demonstrated coat colour and haemoglobin mosaicism, were produced. These were examined daily (birth to 2 months) and weekly for the following 4 to 10 months in different animals, for clinical features of muscular dystrophy.

An estimate of gross muscle function in the mature chimaeras was obtained by recording the maximum isometric twitch of their anterior tibialis muscles in response to supra-maximal nerve stimulation.

The histological appearances of the muscles from chimaeras were compared with those of normal and of dystrophic mice. Individual identified muscles were dissected out and a 2 mm section, taken across the middle of the muscles, was processed for subsequent preparation of 1 μ m Epon sections; the remainder of the muscle was frozen in liquid nitrogen and stored at -70° C for subsequent genotype analysis.

Genetic marker

The dystrophic embryos used in this chimaera preparation had the *Mod-I^b* genotype for malic enzyme (E. S. Russell, personal communication). The normal embryos were determined to have a *Mod-I^a* genotype for the same enzyme. The subsequent analysis depended on the recognition and relative quantitation of the *Mod-I^a* and *Mod-I^b* gene products in the muscles investigated. This was achieved by starch gel electro-

phoresis, which enables the clear resolution of the isozymes of malic enzyme. *Mod-I^a* and *Mod-I^b* genes code for the subunits of the enzymatically active tetramere, malic enzyme⁷. In the *Mod-I^a/Mod-I^b* heterozygote where a and b subunits are simultaneously produced⁸ and randomly associate, five tetrameric forms, aaaa, aaab aabb, abbb, bbbb are electrophoretically resolved. In the dystrophic \longleftrightarrow normal chimaeras, the presence of b subunits observed by resolution of the *Mod-I^b* isozyme or hybrid bands indicates the contribution of genetically dystrophic nuclei. Subunits of a type, forming the *Mod-I^a* isozyme or hybrid bands, could only be derived from the genetically normal nucleus. The descriptions of nuclei as 'normal' or 'dystrophic' is based upon this isozyme characterisation. The hybrid band feature of this isozyme system was used to differentiate muscles with mosaic fibres, that is, fibres with both normal and dystrophic nuclei within the same cytoplasm, from muscles where there were mixtures of fibres, each of which had only normal or dystrophic nuclei, but not both. In the latter case, only the parental bands, aaaa and/or bbbb would be detected⁹.

If the enzymatic activities of the five tetrameric types were equal, in the heterozygote, the theoretically expected 1:4:6:4:1 ratio from random association of the subunit types into tetrameres would be observed in the ratio of activity developed on the starch gel. This ratio was not observed in the original description of the *Mod-I* tetrameric types⁷ nor was it seen in the electrophoretic system used in the present experiment. The measured density ratio of the five bands in the heterozygote after enzymatic staining on the starch gel was 1.00 aaaa, 2.19 aaab, 2.53 aabb, 0.59 abbb, and 0.10 bbbb (Fig. 1). The assumption was made therefore that each tetramere type had a unique enzymatic activity. To measure the *Mod-I^a* and *Mod-I^b* gene products the observed activity for each tetrameric type was corrected by unique factors to regenerate the theoretical 1:4:6:4:1 ratio. These factors, derived from heterozygote electrophoretograms, were subsequently applied to the electrophoretograms of the chimaera muscles before calculation of the relative *Mod-I^a* and *Mod-I^b* genotypes.

Muscle analysis

The behaviour of all the chimaeras was not distinguishable from that of normal animals of the same age. At no time could convincing features of muscular dystrophy be demonstrated by any of the recognised stresses and manipulations known⁶.

FIG. 2 Maximum isometric twitch of anterior tibialis muscles. Mouse: F1 is SWV-C57Bl/10J; *dy²³* is C57Bl/6J *dy²³/dy²³* dystrophic; C is chimaera (C11, 9, 8, 10, 16 are dystrophic \longleftrightarrow normal; C17 and 7 are normal \longleftrightarrow normal). Muscles: numbers are number of muscles analysed; L and R is left and right; broken lines represent suboptimal preparations and are not included in means; C7 left was a technical failure. a, control; b, dystrophic chimaeras; c, normal chimaeras.

FIG. 3 *Mod-I* electrophoretograms and corresponding densitometer traces from C57Bl/6J $dy^{23}/dy^{23} \longleftrightarrow$ SWV $^{+/+}$ chimaera muscles. *Mod-I^a* isoform is on the left of each trace. Frozen muscle samples were weighed, homogenised in 1 ml of H₂O; centrifuged at 3° C for 15 min at 15,000g; the supernatant at 90,000g for 30 min, and freeze dried. The supernatant was reconstituted with H₂O to yield a seven-fold concentration before electrophoresis. Electrophoresis was carried out on a microstarch gel system¹². The buffer system was modified for high voltage (21 V cm⁻¹ after Baker and Mintz⁹). The bridge consisted of 2,000 ml H₂O, 18.8 g citric acid (anhydrous) and Tris base to pH 8.4. Gel buffer was 12.5 ml of bridge diluted to 250 ml with H₂O and re-adjusted to pH 8.4 with Tris base. Electrophoresis was performed at 5° C for 5 h. Malic enzyme was demonstrated by the assay of Henderson¹³. Densitometry was carried out directly with glycerine-cleared gels on a Joyce Loebl recording microdensitometer. The trace was integrated by planimetry and the relative a and b subunit composition was calculated.

All the anterior tibialis muscles investigated showed twitch tensions which were either equal to or even larger than those of normal animals which were examined in parallel (Fig. 2).

Electrophoretograms from the majority of dystrophic \longleftrightarrow normal chimaera muscles revealed the activity of both dystrophic and normal nuclei (Fig. 3). The constitutional genotype of the muscles examined ranged from completely normal (Fig. 3a) through many heterozygous-like forms (Fig. 3b-g) to muscles with a mixed population of totally normal and totally dystrophic fibres (Fig. 3h). Although no muscles without some normal nuclei were observed, in some muscles as many as 94% of the nuclei were estimated to be of dystrophic genotype. Amongst these muscles with a high proportion of dystrophic nuclei, some had very large populations of fibres with only dystrophic nuclei (Fig. 3h). The dystrophic nuclei composition of 47 muscles, pooled from five chimaeras, was 58%. This estimate of dystrophic geno-

FIG. 4 Left biceps femoris muscle of chimaera No. 10. Note the normal morphology of muscle fibres. Magnification $\times 153$ approximately.

type indicates that no obvious selective death of genetically dystrophic nuclei had taken place either during myogenesis or in the mature muscle.

In the two normal \longleftrightarrow normal chimaeras, in which the *Mod-I^b* subunits were derived from C57Bl nuclei without the dystrophic genotype, 10 muscles were pooled in a similar fashion for genotype analysis. In these, the *Mod-I^b* genotype was estimated to be 82%. This higher value for *Mod-I^b* nuclei probably reflects the small sample size, and not a selective advantage of *Mod-I^b* cells, since individual muscles of these normal chimaeras had from 3% to 94% *Mod-I^b* nuclei.

Since the hind limbs show the earliest and most extensive dystrophic clinical symptoms in dystrophic mice, histological examination was made of hind limb muscles in chimaeras which demonstrated extremes of genetic constitution. Minor features of dystrophic muscle pathology, such as central nucleation, were observed in very few fibres in every dystrophic \longleftrightarrow normal chimaera muscle examined. No correlation of these minimal pathological features and the constitutional genotype was observed. Thus in Fig. 4, the left biceps femoris muscle of chimaera No. 10, had 83% dystrophic genotype, and the only detectable abnormality was the occasional central nucleus. Conversely, the left biceps femoris of chimaera No. 16, with no detectable dystrophic

FIG. 5 Left biceps femoris muscle of chimaera No. 16. Note frequency of central nucleation and the presence of coagulation necrosis. Magnification $\times 510$ approximately.

genotype, demonstrated relatively more extensive pathological involvement than all the other muscles examined, that is, degenerating fibres and fibres with central nucleation grouped across the sections (Fig. 5).

These results from chimaeric mice are not compatible with a primary myopathy in murine muscular dystrophy. It could be argued that a small population of normal nuclei, which support synthesis of some postulated chemical, deficient within the fibres of dystrophic muscle, could prevent dystrophic pathology. This seems unlikely, however, because muscles with a high or very high dystrophic genotype, including those with large populations of completely dystrophic fibres, appeared otherwise normal. Furthermore, genetically normal muscle showed pathological changes; which suggests that, at least in the mosaic environment, some entirely extramuscular factor is primarily responsible for the muscle degeneration.

Finally, it has been suggested that these artificial chimaeras show mosaicism similar to that expressed in human females as a consequence of random inactivation of one X chromosome¹⁰. A variable muscle constitutional genotype has long been considered to account for the variable pathological features observed in females carrying the X-linked form of Duchenne muscular dystrophy¹¹. If the primary lesion in Duchenne dystrophy is homologous to that in murine dystrophy, this concept must be re-evaluated. A variable mosaicism in some other cell type, possibly the motor neurones, could account for this observed clinical variability.

I thank Dr James R. Miller for support and encouragement, Dr F. G. Biddle for advice and help; Drs H. McClelland, M. T. Hollenburg and R. Stace-Smith for use of facilities; and Dr J. Diamond for help in the preparation of the manuscript. This work was supported by grants from the Medical Research Council of Canada and the Muscular Dystrophy Association of Canada to Dr J. R. Miller. I was in receipt of a predoctoral fellowship from the Muscular Dystrophy Association of Canada during the course of this investigation.

Gene dosage compensation in metafemales (3X; 2A) of *Drosophila*

John C. Lucchesi, John M. Rawls, jun.* & Gustavo Maroni

Department of Zoology and Curriculum in Genetics, University of North Carolina, Chapel Hill, North Carolina 27514

The X chromosome of Drosophila provides a unique system for the study of modulation of eukaryotic gene activity.

IN *Drosophila*, dosage compensation, that is, the equalisation of X-linked gene products in males and females, has been reported for RNA synthesis, enzyme activities and terminal phenotypic products¹⁻³. In contrast to mammals, where dosage compensation seems to be mediated by inactivation of one of the two X chromosomes in somatic cells of diploid females, there is good evidence that in *Drosophila* both X chromosomes are active in all cells of the female soma⁴ although the level of activity of each is half that of the single X in a male.

This observation has been extended recently to triploid females (3X;3A where A is one set of autosomes)⁵⁻⁸. Furthermore, in male-like triploid intersexes (2X;3A), the X chromosome was reported to function at a level intermediate between the normal male and female levels. Thus X-linked gene activity seems to be correlated with the rela-

tive number of X chromosomes and sets of autosomes in the genome: activity is high in males where the X/A ratio is 0.5, intermediate in triploid intersexes where the X/A ratio is 0.66 and low in diploid or triploid females where the X/A ratio is 1.0. To test this correlation we have measured X-linked and autosomal gene activity in metafemales (3X;2A) where the higher X/A ratio of 1.5 might be expected to yield a relative activity per gene dose even lower than that characteristic of females. That this may be the case was suggested by the observation that metafemales and females homozygous for an eye colour hypomorphic mutation have the same phenotype⁹. Our results indicate that enzyme activity and rates of RNA synthesis are similar in metafemales and in normal females and, therefore, that X-linked gene activity expressed on a per gene basis is less in these metafemales than in diploid or triploid females.

We used laboratory stocks of *D. melanogaster* and the genetic markers and symbols are those described by Lindsley and Grell¹⁰. Various doses of the structural gene for 6-phosphogluconate dehydrogenase¹¹ (*Pgd*⁺) were obtained using *T*(1 → 3)*w*^{sc}. This rearrangement consists of a transposition of a small segment of the X chromosome, including *Pgd*⁺, into chromosome 3. The two elements of the

† Experiment A, flies produced by mating *e/e* females to *Df(1)w^{sc}, v f/Y*; *Dp(1 → 3)w^{sc}, e⁺/e* males. Experiment B, flies produced by mating *e/e* females to *y w spl/Y*; *Dp(1 → 3)w^{sc}, e⁺/e* males.

‡ These values are corrected for an estimated 6% level of 6PGD activity in the G6PD assay using an extract from normal females.

translocation are *Df(1)w^{sc}*, the deficient X chromosome, and *Dp(1 → 3)w^{sc}*, the duplication-bearing autosome. Females homozygous for the recessive marker *ebony* (*e*) were crossed to either *Df(1)w^{sc}, v f/Y*; *Dp(1 → 3)w^{sc}, e⁺/e* males or to *y w spl/Y*; *Dp(1 → 3)w^{sc}, e⁺/e* males. Full-grown third instar larvae were collected and sorted according to sex and *ebony* (black spiracles) or non-*ebony* (wild type, brownish spiracles) phenotype. The first cross yields *ebony* male and female larvae bearing one dose of *Pgd*⁺ and non-*ebony* male and female larvae bearing two *Pgd*⁺ doses. The second cross yields *ebony* male larvae bearing one *Pgd*⁺ dose, non-*ebony* male and *ebony* female larvae bearing two *Pgd*⁺ doses, and non-*ebony* female larvae possessing three doses of *Pgd*⁺.

To produce metafemale larvae, *C(1)RM, y v f/Y* attached-X females were crossed to *y v f-y⁺/Y* males. (The X chromosome represents an X-ray-induced detachment of the attached-X, marked with a small duplication bearing the wild type, dominant allele of *yellow*, *y⁺*.) Female larvae with yellow mouth parts and setae were controls (2X;2A), those with black mouth parts and setae were metafemales, while all male larvae had black mouth parts. To improve the yield of emerged adult metafemales, *C(1)RM, y v f/Y* females were outcrossed to *+ / Y* males of a Samarkand wild-type line. The phenotypic distinction of the various larval types was the same as in the previous cross. While crosses were usually incubated at $25^\circ \pm 1^\circ \text{C}$, some cultures of attached-X females by wild type males were maintained at $20^\circ \pm 1^\circ \text{C}$ to obtain larvae for autoradiography.

Larval samples were homogenised in conical ground-glass

homogenisers at a ratio of fifteen larvae per ml of distilled water; adult samples were homogenised at a concentration of 20 mg live weight per ml of distilled water. After 20 min, samples were centrifuged for 40 min at 12,000 *g* and the clear supernatant was used as a crude enzyme extract. Throughout preparation all extracts were maintained at 0° – 5°C .

Larval fat body samples were obtained by chopping 50 mature third instar larvae with a razor blade in a few drops of 2% sucrose. After transfer to a test tube containing approximately 5 ml of cold 2% sucrose, fat bodies and other organ fragments were dislodged from the body wall casings by aspirations into a Pasteur pipette. After standing for 20 min at 0°C , most of the loose fat body fragments floated to the surface, remarkably free of other tissue. The fat body layer was drawn off and its volume adjusted to 1 ml with distilled water. After brief sonication, the extract was centrifuged for 20 min at 12,000 *g* and enzyme activities were determined in the supernatant.

We measured activities of glucose-6-phosphate dehydrogenase (G6PD, EC 1.1.1.49), 6-phosphogluconate dehydrogenase (6PGD, EC 1.1.1.44), α -glycerophosphate dehydrogenase (α -GPDH, EC 1.1.1.8), NADP-dependent isocitrate dehydrogenase (IDH, EC 1.1.1.42), and alcohol dehydrogenase (ADH, EC 1.1.1.1). Substrate solutions and assay conditions for the first four enzymes have been described before⁵. ADH was measured using the reaction mixture of Jacobson *et al.*¹². All dehydrogenase activities were monitored spectrophotometrically at 340 nm and enzyme activities are expressed as μmol of NAD⁺ or NADP⁺ reduced

per min per mg protein at 29° C. Extract protein concentration was determined using the method of Lowry *et al.*¹³. Mean enzyme activity values were compared using Student's *t* test.

For autoradiography, salivary glands were dissected out of late third instar larvae in Ephrussi-Beadle solution. They were incubated for 5 min in ³H-uridine (Amersham Searle, 30 Ci mmol⁻¹) at a concentration of 20 μ Ci ml⁻¹. Fixation and squashing, preparation, exposure and development of autoradiographs were as previously described⁷. The rate of RNA synthesis was measured in segment 1-3C of the X chromosome using an autosomal segment—the right arm of chromosome 2 (58F-60)—as an internal control. Grains were counted in nuclei where both segments were unobstructed. Average values of grain counts over the X segment (\bar{X}) and the autosomal segment ($\bar{2R}$) were obtained for every gland. The slope of the regression line of \bar{X} on $\bar{2R}$ is a measure of the average increment in the number of grains over the X which accompanies a unitary increment in the number of grains over the autosome. This slope, represented by the regression coefficient *b*, is a measure of the rate of RNA synthesis in the X relative to that in an autosome.

Enzyme levels

Before examining the dosage compensation of metafemale enzyme levels in larvae, we had to establish that the relationships between regular adult male and female enzyme levels are also evident in larvae. As Table 1 shows, we found this to be the case. Two of the four enzymes studied, 6PGD and G6PD, are X-linked^{11,14} while the known structural genes for ADH and IDH are linked to chromosomes two and three, respectively^{15,16}. The autosomal enzyme levels of male and female larvae are equivalent and dosage compensation seems to be fully operative, as evidenced by the similarity in G6PD and 6PGD activities in the two sexes, and by the observation that each *Pgd*⁺ dose in female larvae with one, two or three doses of this gene produces approximately half the amount of 6PGD that it produces in male larvae with one or two doses of the gene.

Enzyme activities of metafemales and normal diploid females are presented in Table 2. Activities of male sibs are

included as an internal control. Measurements were performed on extracts of whole larvae, larval fat body, 0-1 h and 9-10-h-old emerged adults. α -GPDH, the gene for which is located on the second chromosome¹⁷, was measured instead of ADH in these experiments. No male and female values differed from each other. Metafemales, on the other hand, showed greater variability, with values often in excess of those of control females. In most cases, however, both X-linked and autosomal enzymes seemed to be affected. For example, metafemale larvae have significantly higher specific activities of 6PGD and α -GPDH than euploid controls. This may be the consequence of the longer time required by metafemales to reach the end of the third larval instar, leading to the preferential accumulation of certain soluble proteins. When we measured enzyme activities in the larval fat body, which is metabolically highly active, all soluble dehydrogenases assayed were significantly higher in metafemales than in euploid controls. Emerged adult metafemales, on the other hand, had activities either reduced (α -GPDH and IDH in 0-1 h-old adults) or equivalent to those of controls.

X-linked enzyme activity measurements can be normalised in relation to either α -GPDH or IDH activity, since metafemales and control females each contain two doses of the structural genes of these enzymes per genome. Table 3 contains per gene activities obtained by dividing the normalised X-linked activities of metafemales by three and of females by two. Taken together and evaluated in the light of the generalised physiological disturbances of metafemales, these results indicate that X-linked genes are substantially less active in metafemales than in normal females, and that the presence of a third X chromosome in the genome of the former flies does not mediate a structural gene dosage response, that is, a 50% increase in X-linked gene product per cell. This conclusion is substantiated by the autoradiographic monitoring of X chromosome activity.

RNA synthesis

The results of the study of ³H-uridine incorporation by metafemale and diploid female larval salivary gland chromosomes are presented in Table 4. To compare metafemale and female grain counts properly, it must be remembered that in the former the X element contains three synapsed chromo-

TABLE 4 RNA synthesis in metafemales and females

Sex	No. nuclei	No. glands	Average [X]	Average [2R]	<i>r</i>	<i>b</i> \pm s.e.
Metafemales	76	9	59.17	44.74	0.98	0.96 \pm 0.07
Females	84	9	60.52	52.13	0.97	1.10 \pm 0.10

Average [X] and average [2R] = overall average of grain counts over X and 2R segments, respectively.

r, Correlation coefficient of the mean grain counts for individual glands, [X] and [2R].

b, Regression coefficient of [X] on [2R]. Not significantly different.

The metafemale values for average [X] and *b* were corrected for differential self-absorption.

somes instead of two and therefore absorbs more β particles than does the X element of control females. Taking the efficiency of X chromosome grain production in males as approximately 20% higher than in females⁷, the values for meta-females were corrected by an increment of 10%.

If the grain counts over the X and autosome are averaged for each gland and a regression line of these averages ($[X]$ on $[2R]$) is established, the slope of this line is the same in males and females (G. Maroni, R. Kaplan and W. Plaut, in preparation) or in triploid intersexes and triploid females⁷. This indicates that the rate of RNA synthesis by the X element relative to the rate of synthesis by the autosomal element is the same in males where the X is single as in females where the X element is made up of two paired X chromosomes; similar conclusions were reached for triploid intersexes (two Xs) and triploid females (three Xs). We

FIG. 1 Schematic representation of X gene activity in individuals of various chromosomal constitutions. The height of the columns represents total gene product per cell; a value of 2 was arbitrarily chosen for diploids. The shaded areas represent activity per gene dose; diploid females were given a value of 1.

found that there was no significant difference between the regression coefficients of metafemales and females, indicating that the rate of RNA synthesis by the trivalent X element of metafemales relative to the rate of RNA synthesis by an autosomal element is indistinguishable from that of normal females. Another way of expressing this result would be to say that an X chromosome in a metafemale synthesises, per unit time, only two-thirds of the RNA which it normally does in a female.

Compensation and modulation

When our findings are pooled with those derived from enzymological and autoradiographic comparisons of diploid males and females^{1,2}, it is evident that the overall expression of X-linked genetic activity (that is, the total amount of X-linked gene product) in diploid cells is independent of the number of X chromosomes within the cell. Similarly, comparisons of triploid genotypes³⁻⁸ suggest that within triploid cells, the phenotypic level achieved by X-linked genes is independent of the number of X chromosomes present in the cell. In triploid cells, however, the overall level of X-linked gene activity is approximately 50% greater than that of diploid cells^{5,8}. Because of the latter relationship, Maroni and Plaut^{7,8} proposed that dosage compensation is mediated by an autosomally-derived factor which is rate-limiting in the expression of X-linked genes. Our current finding with respect to the equivalence of X-linked activity

in metafemales and diploid females agrees with this hypothesis.

In spite of differences in the means of implementation of dosage compensation, there is a similarity between *Drosophila* and mammals. Lyon¹⁸ has suggested that the somatic differentiation of X chromosomes into active or inactive states involves interplay of genes on the X and an autosome. This suggestion is based on the observation that in human aneuploids with two sets of autosomes and varying numbers of sex chromosomes (XXY; 2A,3X; 2A or 4X;2A) only one X remains active, while in triploids (XXY;3A or 3X;3A) or tetraploids (XXYY;4A) two X chromosomes can remain active^{19,20}.

The modulation of gene activity is a central problem in the study of genomic expression. Different levels of induction can be achieved easily with microbial systems by manipulation of effector or terminal product concentrations. Analogous circumstances are much more difficult to establish in the case of multicellular organisms. Therefore, the X chromosome of *Drosophila* is of unique interest in this respect since four levels of activity have been recorded for genes on this chromosome: the highest level is in males, the lowest in metafemales, and two intermediate levels are in triploid intersexes and euploid females (Fig. 1). These relative levels of activity seem to be established comparatively early in development, before the late larval stages. Elucidation of the causative factors responsible for a given level of X-linked gene activity in *Drosophila* should contribute to the understanding of other examples of eukaryotic genome modulation.

This investigation was supported by a research grant, a genetics training grant and a research career development award (to J. C. L.) from the National Institute of General Medical Sciences.

Statistical analysis of close pairs of QSOs

THE observation of close pairs of QSOs with very different redshifts has been suggested to be evidence in support of the noncosmological redshift hypothesis^{1,2}. The statistical arguments used by Stockton¹ and by Wampler *et al.*² have recently been attacked by Bahcall and Woltjer³ on the ground that the method used is one of *a posteriori* statistics. Statistics aside, they have ignored the point that in one case², the evidence is not only based on close proximity of the two QSOs but also on two coincidences in wavelengths in the spectra of the two objects. Although the argument against *a posteriori* statistics is correct in the absolute sense, this method is widely used in astronomy and has generally been accepted, except in cases in which the hypothesis under consideration has not reached the point of general acceptability. The redshift controversy is a good example of this. Evidence as to the existence of non-cosmological redshifts must, because we have few ways of measuring distance, depend upon finding conflicts between distances derived from the redshifts (assumed cosmological) and distances derived in other ways⁴—either through statistical arguments or by finding luminous connections between pairs of objects. If, as seems to be the case, most workers use the redshift as the prime criterion of distance, and subordinate other methods of measurement to it, no solution to the problem is possible.

One or two examples of the prejudicial approach used in this problem will suffice:

(1) Several cases of QSOs with low redshift close to small groups of galaxies, and with redshifts similar to those of one or more members of the respective groups, have been found. Although some of these associations may be real, the statistical evidence is not convincing⁵; nevertheless, these juxtapositions are cited by many as proof of the cosmological origin of QSO redshifts. It is instructive to examine some of the analyses which attached statistical significance to such associations. For example, Gunn⁶ found a small group of galaxies near the QSO PKS2251+11 ($z = 0.33$) agreeing in redshift within the observational uncertainty ($\Delta z \approx \pm 0.01$). He finds that the brightest member of the group, with a calculated absolute magnitude -21.2 , lies $28''$ from the QSO; then he asks: "What is the probability of finding a galaxy of absolute magnitude -21 or brighter within $30''$ of a random position and within $3,000 \text{ km s}^{-1}$ of a given redshift near 0.3 ?" The answer, 0.001 before multiplying by the number of tries, is then purported to be "a realistic assessment of the probability of a chance coincidence". While the choice of $3,000 \text{ km s}^{-1}$ can be justified since it follows from the observational uncertainty, the choices of the magnitude limit, -21 , and the separation limit $30''$ are obviously predicated upon the observed values -21.2 and $28''$, respectively, and thus constitute *a posteriori* information.

(2) Another good example is found in a paper by Wolf and Bahcall⁷. They wish to argue that a galaxy in a cluster is physically associated with the N-system Ton256. We quote them as follows: "There appears to be a galaxy about $8''$ from Ton256; the redshifts of the galaxy and Ton256 are identical, to within the observational error of 300 km s^{-1} . The density of galaxies in the central region of the cluster is $\sim 0.08 \text{ galaxies (arc min)}^{-2}$; so the probability of having a galaxy

appear within $8''$ from the QSO, assuming a random distribution of the galaxies near the center of the cluster, is only about 0.4% . We thus assume that the galaxy is really associated with the QSO and is in a bound orbit around the QSO." Again, this is a classic piece of statistical analysis argued *a posteriori*, presumably considered acceptable because the redshifts of the two objects are the same.

In what follows we reconsider the pairs already discovered and then make an *a priori* calculation based on realistic parameters such that a test involving the discovery of further close pairs of QSOs may enable a significant statement to be made.

Let $\Gamma(< m)$ be the sky density of QSOs brighter than m . Then the expected number lying by chance within an angular separation θ of N arbitrary coordinates is

$$\langle n \rangle = 2.4 \times 10^{-7} N \Gamma(< m) \theta^2, \quad (1)$$

with Γ expressed in $(\text{arc deg})^{-2}$ and θ , in arc s. A plot of $\langle n \rangle$ against θ for various $N\Gamma$ is shown in Fig. 1. For N corresponding to the number of QSOs with known redshifts (~ 300), and $\Gamma(m_b < 19.4)$ taken from the Sandage-Luyten survey [$\sim 5 \text{ QSO (arc deg)}^{-2}$], the value for the product $N\Gamma$ is $\sim 1,500 \text{ tries per QSO (arc deg)}^{-2}$. This number could be increased to $\sim 3,000$ by extending the survey to $m_b < 20$. Of course, it is always possible to consider a more restricted sample, yielding a smaller value for $N\Gamma$, but to obtain a value much larger than $3,000$ would require deep plates

Fig. 1 Dependence of the expected number of apparent pairs upon pre-selected class intervals defined by the maximum angular separation θ to be included and the product of the number of tries N and the sky density $\Gamma(< m)$ of QSOs brighter than the adopted completeness limit m of the sample to be considered.

or deep scans around each of the known QSOs. From a practical point of view it would be difficult to go to $m_n = 21$ on the Palomar Sky Survey because objects at the very limit of the Survey, lying say $5''$ from a brighter object, will tend to be missed and in any case would be very difficult to examine spectroscopically.

The QSO 1548+115a lies about $5''$ from the previously identified QSO 1548+115b (ref. 2). Using the observed separation, the expected number of such pairs, for NT ($m > 19.4$) $\approx 1,500$, is only about ~ 0.01 ; however, since this choice of separation θ is based on *a posteriori* information, the quoted probability is only an approximate lower limit to a realistic *a priori* probability. In order to estimate an upper limit to the *a priori* probability, we can consider the class interval determined by the next nearest separation known—namely, the $35''$ separation of Ton155 and Ton156 (ref. 1). Adopting $\theta = 35''$, the number of pairs with smaller separations expected by chance is ~ 0.4 (see ref. 3).

The statistical significance of the pair 1548+115a,b is thus not well defined; it ranges from $\sim 99\%$ confidence to about 60% . Consequently, the *a priori* statistical significance of this pair cannot be demonstrated. Nevertheless, the proximity of the association is curious, particularly in view of the spectroscopic coincidences already mentioned. Unless additional evidence is uncovered, however, the proximity of 1548+115a,b will remain just a curiosity cited by some as evidence for non-cosmological redshifts, but disregarded by others as a mere coincidence. We therefore propose the statistical test described below.

The vicinity of all ~ 300 QSOs with known redshifts has not been examined closely, and, in fact the method of identification of QSOs from radio positions may have biased the sample against the discovery of close pairs because when a suggested identification close to the radio position is found to be a QSO, no further examination of other nearby objects is usually undertaken. Consequently, more associations may exist (compounding the probabilities). We propose, therefore, that the vicinity around each known QSO be examined for possible conjugates down to $m_n \approx 20$, since it should be feasible to examine any such candidates spectroscopically. For $NT \approx 3,000$, the expected number with chance separations less than $\theta = 10$ arc s is only $\langle n \rangle \approx 0.08$ (see equation 1 and Fig. 1). Thus, the discovery of a second pair of QSOs—or two more pairs of QSOs if the known case 1548+115a,b is excluded from the sample—would be statistically significant at 99.5% confidence, based on *a priori* class intervals.

Absorption of high energy heavy nuclei and γ rays at the surface of hot neutron stars

SINCE the discovery of pulsars and their association with rotating magnetic neutron stars, it has been realised that pulsars can efficiently accelerate particles to high energies and effectively contribute to the observed cosmic-ray density in the Galaxy. Acceleration of particles to very high energies by the low frequency electromagnetic waves beyond the light cylinder is one mechanism proposed^{1,2}. Others³⁻⁵ have considered the possibility of accelerating particles by the electric field near the surface of the neutron star arising from non-zero $\mathbf{E} \cdot \mathbf{B}$. High energy photons are also likely to be produced in association with these particles and these have been observed from the Crab pulsar. Presumably, younger pulsars may radiate larger numbers of more energetic γ rays.

Though pulsars are potential sources of very high energy particles and γ rays, it is not clear whether the radiation can escape the pulsar environment and reach interstellar space. Various absorption processes can contribute to the destruction of these radiations. Absorption of high energy γ rays in their interactions with the radiation field of the pulsar may occur⁶⁻⁸. Destruction of high energy cosmic rays, especially the photodisintegration of heavy nuclei in the vicinity of pulsars, has also been considered^{9,10}. Heavy nuclei may be destroyed by fragmentation in the high density nebular matter surrounding pulsars in their early stages¹¹. All these processes become important in the early stages of pulsars because of the simultaneous presence of particles of very high energy and large radiation and matter density.

Here I point out that high energy heavy nuclei and γ rays may also be absorbed because of their interactions with the blackbody photons emitted from the surface of the hot neutron star. Neutron stars have surface temperatures greater than 10^7 K when they form and subsequently the temperature decreases¹². Tsuruta *et al.*¹³ have carried out improved cooling calculations taking into account the influence of superfluidity of the matter of the neutron star, the magnetic field and other factors. Their calculations show that for the first 100 yr the surface temperature is 10^7 K and remains greater than 5×10^6 K for another few hundred years for several models. So there is a high density of photons close to the neutron star during the early stages. It is precisely during this period that pulsars lose most of their energy and accelerate particles to high energies. I have discussed the implication of high surface temperature for the radio emission of pulsars elsewhere¹³; here I concentrate on other effects.

If a is the radius of the neutron star and T its surface temperature, the differential spectrum of photons emitted from the surface is

$$n(\epsilon) d\epsilon = \frac{2\epsilon^2}{h^3 c^2} (e^{\epsilon/kT} - 1)^{-1} \text{ photons (cm}^2 \text{ s sr erg)}^{-1} \quad (1)$$

Considering the interaction between a γ ray at O, at a distance R from the centre, travelling radially, and photons from the surface of the neutron star (see Fig. 1) the optical depth for γ - γ interaction is

$$\frac{d\tau}{dR} = \iint (2\pi a^2 \sin \alpha d\alpha \cos \phi) (r^{-2}) \cdot (1 - \cos \beta) n(\epsilon) d\epsilon \frac{\sigma(E_\gamma, \epsilon)}{c} \quad (2)$$

Here $\sigma(E_\gamma, \epsilon)$ is the cross section for pair production in the collision of a γ ray of energy E_γ with a photon of energy ϵ , the term $(2\pi a^2 \sin \alpha d\alpha \cos \phi)$ is the element of area normal to OA, the term r^{-2} represents the inverse square reduction and the term $(1 - \cos \beta)$ takes care of the relative velocity between the two photons. The integration with respect to α

FIG. 1 The interaction between a γ ray or heavy nucleus with blackbody photons from an elemental surface of the neutron star (see text).

is to be carried out between the limits $\alpha = 0$ and $\alpha = \cos^{-1}(a/R)$. The cross section for γ - γ pair production has a threshold $\epsilon E_\gamma(1 - \cos\beta) = 2m^2c^4$. Choosing the variables $x = a/R$, $s = \epsilon E_\gamma(1 - \cos\beta)/2m^2c^4 = s_0 z$ where $s_0 = \epsilon E_\gamma/2m^2c^4$ and $z = (1 - \cos\beta)$, equation (2) becomes

$$\frac{d\tau}{dR} = \iint 2\pi x^2 n(\epsilon) (1/2x^2 s_0^2) \frac{\sigma(s)}{c} s ds \quad (3)$$

Following the treatment of Gould and Schreder¹⁵ I express ϵ in units of kT and introduce the variable $\nu = 2m^2c^4/(E_\gamma kT z_m)$ where $z_m = (1 - \cos\beta_m)$ and $\beta_m = \sin^{-1}(a/R)$. After performing the integration and rewriting the terms in a manner similar to that of Gould and Schreder

$$\frac{d\tau}{dR} = \frac{\alpha^2}{2\pi\Lambda} \left(\frac{kT}{mc^2}\right)^3 [1 - (1 - x^2)^{1/2}]^2 f(\nu)$$

where $\alpha = e^2/\hbar c$, $\Lambda = \hbar/mc$ and $f(\nu)$ is the function introduced by Gould and Schreder, who give a plot of $f(\nu)$ against ν . The function $f(\nu)$ has a maximum value of ~ 1 at $\nu \simeq 1$. The total optical depth for γ - γ collision is

$$\begin{aligned} \tau_{\gamma\gamma} &= \int \frac{d\tau}{dR} dR = \frac{\alpha^2}{2\pi\Lambda} \left(\frac{kT}{mc^2}\right)^3 a \\ &\cdot \int_1^0 [1 - (1 - x^2)^{1/2}]^2 f(\nu) \frac{dx}{x^2} \quad (4) \\ &= 1.2 \times 10^3 T_\gamma^3 I_{\gamma\gamma}(\nu) \quad (5) \end{aligned}$$

where $I_{\gamma\gamma}(\nu)$ is the integral in equation (4), T_γ is the surface temperature in units of 10^7 K and a has been taken as 10^6 cm. I have evaluated $I_{\gamma\gamma}(\nu)$ numerically and Fig. 2 shows a plot of $\tau_{\gamma\gamma} T_\gamma^{-3}$ as a function of $T_\gamma E_\gamma$ (GeV).

Photodisintegration of heavy nucleus is most effective in the giant resonance region of photon energy 10 to 20 MeV in the rest system of the nucleus. The cross section increases as $A^{2/3}$ where A is the mass number of the nucleus. Here I shall

consider the disintegration of Fe nuclei. The photonuclear cross section can be written as¹⁶

$$\sigma(y) = c(y - 1) \exp[-(b(y - 1))] \quad (6)$$

where b and c are constants and $y = s/p$, p being the threshold energy for the reaction and $s = (\gamma\epsilon)(1 - \cos\beta)$ $s_0 z$ is the energy of the blackbody photon in the rest system of the nucleus of Lorentz factor γ . Going through a similar treatment as for γ - γ collisions and introducing similar variables I arrive at the following expression for $\tau_{\gamma H}$, the optical depth for disintegration of heavy nuclei:

$$\tau_{\gamma H} = 2\pi\sigma_0 \left(\frac{kT}{\hbar c}\right)^3 a I_{\gamma H}(\nu) \quad (7)$$

where

$$I_{\gamma H}(\nu) = \int_1^0 [1 - (1 - x^2)^{1/2}]^2 f_H(\nu) dx/x^2,$$

$$\nu = p/\gamma k T z_m$$

$$f_H(\nu) = \nu^2 \int_\nu^\infty (e^\epsilon - 1)^{-1} \phi(\epsilon/\nu) d\epsilon,$$

$$\phi(y) = \int_1^y y \bar{\sigma}(y) dy, \text{ and}$$

$$\bar{\sigma}(y) = \sigma(y)/\sigma_0 = \sigma(y)/(10^{-25} \text{ cm}^2)$$

For photodisintegration of Fe nuclei, the cross section can be represented as

$$\bar{\sigma}(y) = 11(y - 1) \exp[-2.7(y - 1)]$$

with a threshold of 13 MeV and a maximum cross section of 150 mb at 18 MeV. With this parametrisation for the cross section, the integral $I_{\gamma H}$ has been numerically evaluated and τ_γ (Fe) calculated. In Fig. 2 I show the plot of τ_γ (Fe T_γ^{-3}) as a function of γT_γ .

The total optical depth for γ - γ collision is shown in Fig. 3 for three different values of temperature. For all temperatures $> 2 \times 10^6$ K, there is a wide range of energies in which

FIG. 2 The quantity $\tau_\gamma T_\gamma^{-3}$ plotted as a function of $E_\gamma T_\gamma$. Here τ is the optical depth for γ - γ and γ -Fe interaction, T_γ is the surface temperature in units of 10^7 K, γ is the Lorentz factor of the Fe nucleus and E_γ the photon energy in GeV.

FIG. 3 Optical depth for $\gamma\text{-}\gamma$ interaction (bottom and left scales) and $\gamma\text{-Fe}$ (top and right scales) plotted as a function of energy for different temperatures. Legend as in Fig. 2. a, 10^7 K; b, 5×10^6 K; c, 10^7 K; d, 5×10^6 K; e, 2×10^6 K.

$\tau_{\gamma\gamma} > 1$. The larger the temperature the higher is the optical depth and wider the range of energy for absorption. In the first few hundred years of a pulsar's life, the temperature is greater than 5×10^6 K, leading to the absorption of γ rays of energy ranging from a few hundred MeV to about 1 TeV. When the temperature is 10^7 K the lower limit extends to about 200 MeV. High energy γ rays can also be absorbed because of pair production in the magnetic field of the pulsar. This has been investigated by Sturrock⁴ who finds that for a surface magnetic field of 10^{12} gauss, this process is important for $E_\gamma \gtrsim 1$ GeV. The absorption mechanisms discussed in this paper not only extends to lower energies but is also independent of the magnetic field (as well as of the beamed radiation that may be associated with the pulsar).

The optical depth for photodisintegration of Fe nuclei is also shown in Fig. 3 for two different temperatures. Here also the optical depth > 1 for $T > 5 \times 10^6$ K over a reasonably wide range of energies. But the range of energies over which absorption occurs is narrower than that for γ rays. In the first hundred years, the surface temperature of the neutron star is $\sim 10^7$ K. It is during this time that the pulsar loses most of its energy and also accelerates particles up to 10^{18} to 10^{19} eV. The highest energies will not be affected by photodisintegration (Fig. 3); but in the range of a few times 10^{12} eV per nucleon to a few times 10^{14} eV per nucleon, Fe nuclei will be disintegrated preferentially. The medium nuclei will be affected less and over a narrower range of energies, since the photonuclear cross section for them is low by a factor about 2.5. Thus, the cosmic-ray nuclei escaping from the pulsar surface will undergo changes in spectra and composition. Such changes have been observed for cosmic rays with energies of tens of GeV^{17,18}. If a large fraction of cosmic rays come from acceleration processes close to the surface of the neutron star, the above mechanism will induce spectral and compositional changes in the range of 10^{12} eV per nucleon to 10^{14} eV per nucleon.

Smoluchowski¹⁹ has pointed out that because of the anisotropic conductivity of neutron star matter, the surface temperature at the poles can be a factor of 2 to 3 higher than the equatorial temperature. For the absorption processes discussed here, it is the polar temperature which is more

relevant; this being higher than the mean temperature used, the absorption may be more severe than indicated.

Duration of dMe flares

GERSHBERG and Shakhovskaya¹ have suggested that the time scales of flare development depend principally on the peak amplitude of flare events, implying that stronger events last longer. They support their contention with observations taken from eleven flare stars. In an earlier investigation of flare decay rates I concluded that time scales are intrinsic properties of the stars themselves².

The relationship determined by Gershberg and Shakhovskaya from their data takes the form

$$\log_{10} \left(-\frac{dL}{dt} \right)_1 = 0.75 \log_{10} L_{\text{peak}} + \text{constant} \quad (1)$$

where $(-dL/dt)_1$ is the decay rate on the light curve chosen in a uniform manner and L_{peak} is the peak radiation loss. The corresponding relationship derived by myself, and put in the same form, is

$$\log_{10} \left(-\frac{dL}{dt} \right)_K = \log_{10} L_{\text{peak}} + AM_{\text{bol}} + \text{constant} \quad (2)$$

where M_{bol} is the stellar bolometric absolute magnitude and A is a constant very nearly equal to 0.2.

For any given star the observable range of the magnitude of peak event is constrained by the detection threshold of the instruments used and by flare incidence statistics, so that the less energetic flares are observed preferentially on

TABLE 1 Data sets for determining time scale properties in the flares of UV Ceti

stars of lower luminosity (ref. 3 and Fig. 3 in ref. 1). Because of these effects a biased result is difficult to avoid unless care is taken. Figures 1 and 2 of Gershberg and Shakhovskaya¹ show this effect: the flares of any given star are found in restricted portions of the diagram. Furthermore, because the intrinsic scatter of the parameters which describe flares is large^{2,3}, the relationship presented by these authors could not have been constructed with adequate confidence from observations of a single star. Equation (2) can be made to fit the data of Gershberg and Shakhovskaya as a direct result.

To decide between the alternatives the following two tests are proposed. First, the relationship between peak flare amplitudes and a time scale parameter for the star with the largest homogeneous set of observations is examined. For this purpose my observations^{3,4} of UV Ceti covering the range $9 < U_{peak} < 14.9$ were used. Subtracting $\log_{10} L_{peak}$ from both sides of equation (1), the equation of Gershberg and Shakhovskaya can be written

$$\log_{10} \frac{dU}{dt} = 0.108 U_{peak} + \text{constant} \quad (3)$$

In place of the decay rate, the most densely sampled time scale parameter which I use is the mean duration of half peak light, $T_{0.5}$; other time scale parameters were not measurable for as many of the detected flares. The mean duration and decay rate are inversely related and equation

(3) can therefore be written

$$\log_{10} T_{0.5} = \alpha U_{peak} + \text{constant} \quad (4)$$

where α is -0.108 (ref. 1), or zero (ref. 2).

Table 1 presents the data examined using least squares. The faint cutoff level has been selected 1 mag brighter than the adopted detection limit for the data sets in order to minimise effects of incomplete sampling at the faint event threshold³. Setting U_{cutoff} 0.5 mag fainter altered the value of α by less than one standard error. The values of the coefficient for both instances are

$$\alpha = -0.005 \pm 0.021, \quad 98 \text{ events}$$

$$\alpha = +0.012 \pm 0.025, \quad 132 \text{ events}$$

respectively.

The second test compares the time scales of events of comparable absolute peak energy for stars of different luminosities. Data for Wolf 630 and CoD-31°17815 (ref. 3) suitable for comparison with those of UV Ceti are presented in Table 2. A sufficient range of peak event magnitudes was observed in Wolf 630 to yield a usable value of the coefficient α (-0.012 ± 0.011). As in the case of UV Ceti, there seems to be no significant relationship between the time scales of flares, and peak amplitudes. Because of this, CoD-31°17815 is the most luminous star used in the proposed comparison, even though the observed range of peak magnitudes of events is still too small to allow a reliable determination of the coefficient α .

Figure 1 presents all the data used in this investigation. A correlation analogous to that described by Gershberg and Shakhovskaya is apparent at first glance: the longer time scales are found in the stronger events. But the weakest events detectable for each star depend strongly on stellar luminosity, colour and parallax, and so the effect is deceptive. For the three stars taken together the data are complete only for flares brighter than $M_{V,peak} = 15.06$. If only this portion of the diagram is considered, the apparent correlation disappears completely. Comparing mean time scales of events lying in the range $14.0 < M_{V,peak} < 15.0$, the flares of shortest duration are those of UV Ceti, and the longest lasting are those of CoD-31°17815. The result is shown in Table 3. From these results it is difficult to conclude that the event durations are distinguishable by their peak amplitudes. But they correlate with stellar absolute magnitude as found by Haro and Chavira⁵. A linear relationship describing the effect, is

$$\log_{10} T_{0.5} = 1.084 - 0.119 M_V \quad (5)$$

The analogous equation of Gershberg and Shakhovskaya¹ yields values for $\log_{10} T_{0.5}$ of -0.81 , -0.41 and -0.24 , for UV Ceti, Wolf 630 and CoD-31°17815, respectively.

Gershberg and Shakhovskaya do not explicitly state that their results apply to flare phenomena on isolated stars and indeed the present analysis indicates that no such relationship applies to isolated flare stars: flare durations are not correlated with peak amplitudes. Even if a relationship of the sort proposed by Gershberg and Shakhovskaya had been found, it would still not have precluded a relationship between flare time scales and stellar luminosity: a comparison

FIG. 1 Relationship between flare durations at half peak light, $T_{0.5}$ (ordinate) and peak light, on a scale of absolute magnitude, $M_{V,peak}$. \times , UV Ceti; \square , Wolf 630; \bullet , CoD-31°17815. The apparent linear correlation between peak light and mean duration is a selection effect. The data are complete only for events brighter than $M_{V,peak} = 15$. This sector shows no correlation between peak light and event duration.

TABLE 3 Mean values of the event duration parameter $\log_{10} T_{0.5}$ for $14 < M_{U, \text{peak}} < 15$

Star	M_V	$\log_{10} T_{0.5}$	$10^{\log_{10} T_{0.5}}$ (min)	No. of flares
UV Ceti	15.5*	-0.74 ± 0.09	0.184	10
Wolf 630	10.8*	-0.26 ± 0.07	0.552	31
CoD-31 ⁹ 17815	8.9	$+0.07 \pm 0.10$	1.29	13

* Value per component, assuming equal luminosity.

of flares of different stars, which fall in the same range of absolute peak energy levels, shows a strong correlation between the mean event duration and stellar luminosity. In conclusion, it seems that the interpretation of the Haro-Chavira phenomenon proposed by these authors is less appropriate than my interpretation².

Internal origin for lunar rilled craters and the maria?

THE origin of lunar craters has been attributed to both volcanism¹⁻³ and/or impact⁴⁻⁶, although since the return of the Apollo 11 volcanic rocks opinion has favoured an endogenic origin for a greater part of the lunar morphology than was previously accepted⁷.

Evidence for lunar vertical crustal movement is provided by Apollo 15 photographs of dipping structures on Silver Spur (25° 40' N, 3° 58' E)⁸ and by craters containing rilles indicating either uplift⁹ or subsidence¹⁰.

Principal lineaments such as rilles and faults, and craters larger than 10 km containing internal rilles, were drawn on overlays of Orbiter I, II, III, IV and V high and low resolution photographs and transferred to a Mercator projection map (Figs 1 and 2) of the Moon.

Because the morphology of the rilles and their enclosing craters is varied, the internally rilled craters can be divided into a number of subgroups (Fig. 3), by shape and size of the enclosing crater and by the rille pattern on the crater floor.

Small craters are less than 15 km in diameter and the diameter of the floor is less than the rim radius. The large craters are generally greater than 15 km in diameter with the diameter of the floor equal to, or much larger than, the rim radius.

On the near side of the Moon, craters of types I, II and III are situated predominantly around the maria, particularly around the western edge of Oceanus Procellarum, with most situated between the maria and the outer limit of the parallel-sided flat-floored normal rilles (see Figs 1 and 2).

There are too few type IV craters for their distribution pattern to be significant but the type V craters, apart from being found in the vicinity, of type I, II and IV, are also found along the major rifts such as the Rheita Valley. A number are also found within the larger flat-bottomed craters

FIG. 1 Map of major lineaments on the Moon; maria have bold outline, dotted line encloses 'normal' rilles.

which themselves contain internal rilles, for example Einstein.

Whereas there are approximately 300 internally rilled craters on the near side of the Moon, there are only about forty on the far side. Although photographic coverage and resolution of the near side is considerably better than that of the far side, photography of the far side is such that only small craters of those occurring in restricted areas of oblique or non-coverage could be added.

A few of the craters on the far side are associated with maria (Komarov) and some are associated with larger craters (Jules Verne and Poincaré groups). The two large craters Oppenheimer and Schrödinger are also rilled. Small rilled craters are again found within larger flat-floored craters (Aitken, Barbier, and Pannekoek). A few internally rilled craters approximately 40 km in diameter (Hogg and Hutton) do not conform to any apparent distribution pattern.

A depth/diameter plot (Fig. 4) of a number of the rilled craters of types I, II and III on the near side (using data from the Arthur catalogue¹¹⁻¹⁴) shows that the majority are wider than the sharply sculptured, well defined, generally deep 'eumorphic' craters which are represented by the line on the diagram (taken from ref. 15).

Because rilles in older craters are much more subdued than those of younger craters, it can be assumed that the rilles in all internally rilled craters formed at about the same time as the crater floor and not as a result of deformation caused by the proximity of the maria.

Figure 4 shows that rilled craters of Copernican, Eratosthenian and pre-Imbrian ages occur in groups approximately parallel to the line for eumorphic craters, with the progressively older craters plotting further toward a smaller depth/diameter ratio. The craters of Imbrian age, however, occur within the fields of all the other groups. This scatter of craters of Imbrian age could be attributed to error in depth/diameter measurements, incorrect identification, or to the fact that the Imbrian craters were produced differently from those of other periods. It is unlikely that the Arthur catalogue is biased toward Imbrian craters alone and the estimated errors for these craters are insufficient to bring the craters into a restricted group on the plot. The Imbrian craters form the basis of the United States Geological Survey lunar stratigraphy so an incorrect age notation is unlikely.

Thus the difference between Imbrian craters and those of other periods is probably due to a peculiarity in the formation of the former. This could have been because vast quantities of lavas were erupted onto the lunar surface during the Imbrian period and the physical constitution of the Moon

FIG. 2 Distribution map of rilled craters on the Moon; ●, type I; ■, type II; X, type III; +, type IV; ○, type V.

at this time may have been radically different from that of earlier and later periods.

Another problem associated with the origin of the rilled craters is that they occur adjacent to grossly similar craters without rilles. Possible explanations for this are that either the rilles in non-rilled craters are covered by later deposits, or that structural defects in the crust beneath rilled craters may have caused preferential rille development. Counts of craters larger than 1 mm within both rilled and non-rilled craters were carried out on the high resolution Orbiter photographs. The results (Fig. 5) show that in most cases the floors of the non-rilled craters have a higher crater density than the floors of the rilled craters in the same age group, arguing against the possibility of a younger floor covering the rilles. The greater crater density may, however, be due to a high percentage of small endogenic craters.

The simplest explanation for rilled and non-rilled craters is that they have tectonically different origins. If the craters are of impact origin, the rilled craters may have been deeper, or have formed in structurally weaker material which allowed a greater degree of isostatic readjustment after infilling, producing the rilles. If, on the other hand, the craters are of endogenic origin the rilles could have been produced by

either updoming of a diapiric body or subsidence after the evacuation of a magma chamber.

The geographical distribution (Fig. 2) of types I, II and III rilled craters indicates that their formation was also

FIG. 4 Depth/diameter graphs of some rilled craters on the near side; horizontal ruling, pre-Imbrian; vertical ruling, Copernican; unshaded outline, Eratosthenian; ○, Copernican; ▲, Eratosthenian; +, Imbrian; ●, pre-Imbrian.

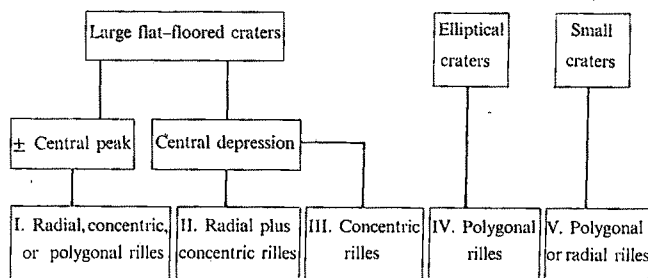

FIG. 3 Classification of rilled craters.

related to the maria. A number of hypotheses can be advanced to account for this relationship depending on whether: (a) both the internally rilled craters and mare basins are of external origin; (b) the craters are of internal origin and the mare basins were formed by impact; (c) the mare basins are of internal origin and the craters were formed by impact; (d) they are both of internal origin.

FIG. 5 Crater density plot for small craters inside rilled and non-rilled craters. Subdivided on age taken from refs 11-14. Rilled: ● = 3; ○ = 2; ◐ = 1. Non-rilled: ◆ = 4; □ = 3; + = 2; + = 1. D, Diameter.

(a) If the rilles within pre-Imbrian rilled craters are of pre-Imbrian age, this first hypothesis is unlikely since bodies would have to have struck the Moon during the pre-Imbrian period within the limits of the then non-existent normal rilles. (These impacts would have been followed by much larger impacts forming the mare basins within the area defined by the pre-Imbrian impacts but not covering such a large geographical area of the Moon. These in turn were followed by smaller bodies which were preserved immediately around the edges of the maria but became swallowed up in the maria. The whole argument sounds very unconvincing.)

(b) If it is argued that the rilled craters are of internal origin as a result of their proximity to the maria, the presence of pre-Imbrian rilled craters would be related to, and surround, an impact site that did not yet exist.

(c) Arguments against this hypothesis are similar to those of (a) and (b) in that it is very difficult to explain the observed crater distributions.

(d) If the mare basins are of internal origin, the distribution of the rilled craters can be readily explained as resulting from their situation in areas of lunar crustal weakness which on the near side of the Moon were centred on the maria. Internal magmatic processes originating in the pre-Imbrian period reached a maximum during the Imbrian period with the formation of the maria by lava eruption and block subsidence. This internal activity steadily declined and became confined to the areas surrounding the maria where normal rilles, mare terraces and rilled craters formed as a result of crustal uplift and subsidence. The differences between the Imbrian rilled craters and those of other periods could be a result of the peculiar state of the lunar crust during the outpouring the mare lavas.

The rilled craters on the far side of the Moon can be similarly interpreted as occurring in areas of lunar crustal weakness. Because the crust is thicker on that side of the Moon¹⁶, either the magma supply was insufficient or magma could not be supplied to the surface at sufficient speeds to produce extensive maria.

It is not necessary to propose an impact origin to account for the areas of weak crust. Structural effects, such as fracturing and faulting, associated with the formation of the lunar grid of Moonwide extent (ref. 2, and G. Fielder and J. L. Whitford-Stark, to be published) could have produced these weaknesses.

The rilled structures in the types IV and V craters could be of volcanic origin; either by cooling contraction of a lava

lake or tholoid doming. Other evidence for their being of internal origin is that many are situated along probable faults, such as the Rheita Valley.

To summarise, if the rilles in large rilled craters are the same age as the enclosing crater, the distribution of the craters precludes them from being anything other than of internal origin and, as a consequence, the maria and their basins must also be of internal origin. The types IV and V craters are also probably related to volcanic processes.

Photo-induced free radicals on a simulated Martian surface

THE atmospheric pressure at the surface of Mars is about 5.5 mbar and the atmosphere is composed mainly of CO₂ with trace amounts of CO, O₂ and H₂O (refs 1 and 2). The Martian dust has an intermediate SiO₂ content of 60 ± 10% (ref. 3). Although it has been thought that the synthesis in a planetary atmosphere of organic compounds relevant to the origin of life requires chemically reducing conditions, Hubbard and colleagues^{4,5} have reported the synthesis of organic compounds by ultraviolet irradiation (λ > 250 nm) of a solid with a gas mixture adsorbed which is compositionally similar to the oxidised atmosphere of Mars. Since the question whether organic compounds could have been formed on the surface of Mars is of fundamental importance to the concept of chemical evolution and to the interpretation of results from the future Mars Viking Mission molecular analysis experiment, we have attempted to confirm these results while concentrating on identifying the primary process and the reactive intermediates involved. Here we describe the electron spin resonance (ESR) study of free radicals in the ultraviolet irradiation of a simulated Martian surface. (A preliminary account was presented at the Fourth International Conference on the Origin of Life, Barcelona, Spain, June 1973.)

Fig. 1 Formation of CO_2H radicals produced at -170°C by ultraviolet irradiation of CO (15 Torr), CO_2 (15 mmHg), CO (15 mmHg) + CO_2 (135 mmHg), and CO (15 mmHg) + CO_2 (135 mmHg) + O_2 (1 mmHg) adsorbed on silica gel. ○, CO; □, CO + CO_2 ; △, CO + CO_2 + O_2 ; ◇, CO_2 .

The silica gel used in these experiments consisted of 60 to 80 mesh, acid-washed gas chromatograph grade powder. The CO (free of iron carbonyl), CO_2 and O_2 used were Matheson high quality research grade. The vacuum system used to introduce gases had had no previous exposure to mercury. In a typical experiment, the silica gel (200 mg) was placed in an ESR tube (made of Suprasil, 20×0.4 cm outer diameter) and was heated at 180°C for 6 h in a vacuum of 10^{-5} mmHg, then continuously evacuated for 16 h at room temperature. Various gases were then introduced through the vacuum line into the ESR tube and exposed to the silica surfaces. The resultant sample, in the sealed ESR tube, was then placed in an ESR cavity and irradiated with a low pressure mercury lamp through a Vycor filter. Thus the ultraviolet light used for irradiations contained, chiefly, the 253.7 nm line with minor components in the longer wavelength region. Irradiation was usually carried out at -170°C . The ESR spectra were recorded on a Varian V-4500 X-band spectrometer equipped with a variable temperature attachment. The g values were obtained by comparison with the standard value for diphenylpicryl hydrazyl (DPPH, $g = 2.0037$). The estimated error for each g value was about ± 0.0002 . The vapour pressures for all gases indicated below were those observed at room temperature with a calibrated thermal conductivity gauge. These values were arbitrarily chosen for experimental convenience; nevertheless, CO_2 was kept in excess in the systems containing a mixture of gases.

Irradiation of the silica gel alone at -170°C slowly produced a radical species, as evidenced by the appearance of the ESR signal. The spectrum consists of a major peak with $g = 2.0120$ and a minor peak at a field 27 gauss lower ($g = 2.0292$). The g value of the major peak is consistent with the reported g value (2.01) for the OH radical produced in a frozen H_2O medium at -196°C (ref. 6). The same ESR spectrum was obtained more quickly when vapour from dilute aqueous H_2O_2 (vapour pressure, 0.3 mmHg) adsorbed on silica gel was irradiated at -170°C . Both radicals showed the same thermal decay behaviour; the ESR signals disappeared when the samples were warmed to room temperature. Since photolysis of H_2O_2 with 253.7 nm light results only in OH formation⁷, we conclude that this major peak is due

to the OH radical. Exposure of the silica gel to H_2O vapour (5 mmHg) followed by irradiation at -170°C did not lead to enhanced signal intensity due to additional OH radical formation.

When the silica gel was exposed to O_2 (1 mmHg) and then irradiated at -170°C , a new radical species was formed. The spectrum shows g value anisotropy having $g_x = 2.0255$, $g_y = 2.0088$, and $g_z = 2.0037$. It also shows doublet hyperfine splitting of 10 gauss for the peak at g_x because of coupling to a proton. This spectrum is identical with that of the O_2H radical reported by Smith and Wyard⁸.

When a silica gel sample containing CO (15 mmHg), or CO_2 (15 mmHg), or a mixture of CO (15 mmHg) and CO_2 (135 mmHg) was irradiated at -170°C , a different radical was observed. The signal appears at a higher field than the OH radical, and the line shape shows characteristic g -value anisotropy. The g values for this new radical are $g_x = g_y = 2.0024$ and $g_z = 1.9971$, and its isotropic or average g value is 2.0006, which is close to the isotropic liquid g value of 2.0002 reported for the CO_2H radical⁹, and which is in excellent agreement with the average g -value of 2.0005 attributed by Chantry *et al.*¹⁰ to the CO_2H radical formed by gamma irradiation of potassium bicarbonate crystals. Furthermore, the average g value (2.0006) of this radical is below the free spin value (2.0023), indicating that it is unlikely to be the π radical, HCO_2 . But it is consistent with the σ radical, CO_2H , in which the unpaired spin resides on an orbital of approximately sp^2 type¹¹. The g anisotropy of the CO_2H radical indicates that it was formed on the silica surface where it was stable for hours in the dark at -170°C . On warming it decayed rapidly and the ESR spectrum disappeared at about -50°C . The CO_2H radical was the only radical product observed at -170°C when a mixture of O_2 (1 mmHg), CO (15 mmHg), and CO_2 (135 mmHg) adsorbed on silica gel was irradiated. The relative yields of the CO_2H radical obtained under various conditions as estimated from ESR signal intensity are shown in Fig. 1. No ESR signal was observed when CO, CO + H_2O , CO + CO_2 , or CO + CO_2 + O_2 was irradiated at -170°C in the absence of silica gel.

After warming to room temperature, continued irradiation of all previously irradiated samples (CO, CO_2 , CO + CO_2 or CO + CO_2 + O_2 adsorbed on silica gel) resulted in the generation of a third radical species. The line width is narrower (3 gauss, compared with 5 gauss for CO_2H). Furthermore, this radical was stable at room temperature for days, thus, indicating that a new radical was formed. The g values for this radical are $g_x = g_y = 2.0024$ and $g_z = 1.9979$. Comparison of the ESR line shape, line width and g values of this radical with other reported data^{12,13} reveals that this is the carbon dioxide anion radical, CO_2^- . When HCO_2H was adsorbed on silica gel and irradiated at room temperature, an identical ESR spectrum was obtained. These two radicals also show the same thermal decay behaviour.

Results of the present ESR study suggest that the ultraviolet photolysis of CO or CO_2 , or a mixture of CO and CO_2 adsorbed on silica gel at -170°C , involves the formation of OH radicals and possibly H atoms as the primary process, followed by the formation of CO_2H radicals. Although other radicals might also have been formed, microwave power saturation and thermal decay experiments show that the indicated radicals were the principal radical products. The H atoms and OH radicals may be produced by: (i) direct photodissociation of H_2O vapour and/or H_2O physically adsorbed on silica gel; (ii) absorption of the ultraviolet excitation energy by the silica surface with subsequent cleavage of the silanol bonds, ($=\text{Si}-\text{H}$ and $=\text{Si}-\text{OH}$); (iii) energy transfer from silica gel to adsorbed H_2O followed by cleavage of $\text{H}-\text{OH}$ bond; or (iv) a combination of the above. Process (i) seems very unlikely since ultraviolet irradiation was carried out with the wavelength (>253.7 nm) longer than that absorbed by H_2O molecules. Moreover, no ESR signal was observed when H_2O ad-

sorbed on NaCl was irradiated at -170°C with the same light source. In the NaCl system, only H_2O vapour and physically adsorbed H_2O were present. Furthermore, no ESR signal was observed when a mixture of CO (15 mmHg), CO_2 (135 mmHg) and H_2O (1 mmHg) adsorbed on NaCl was irradiated at -170°C . We therefore conclude that either (ii) or (iii) or (iv) is more likely. Similar processes such as photosensitisation of hydrogen dissociation by silica gel¹⁴, and ultraviolet-induced bond cleavages of =Si-OCH_3 and =SiO-CH_3 (ref. 15) have been reported. The energy transfer process (iii) may be of minor importance relative to cleavage of silanol bonds (ii) since there was no significant increase in the ESR signal due to OH radicals during the irradiation of silica gel containing 5 mmHg of H_2O vapour. When silica gel preheated at 450°C (instead of 150°C) was irradiated at -170°C , only a very weak ESR signal of the OH radical was observed. Apparently, at this temperature, most of the silanol groups condensed to liberate H_2O , leaving surface siloxane groups¹⁶.

H atoms were not observed by ESR in our experiments, possibly because of their low concentration and/or rapid combination to form H_2 molecules. Reactions of the H atom and OH radical with CO can form the HCO radical and CO_2H radical, respectively. CO is an efficient scavenger for the OH radical¹⁷; therefore, the formation of CO_2H radical is expected to be favoured. Presumably because of the low concentration of free H atoms available for capture by CO, the CHO radical could not be detected under the conditions of these experiments. In fact, Hubbard *et al.*^{4,5} observed only a very low yield of HCHO as compared to HCO_2H . When CO_2 is adsorbed on silica gel, photochemically produced H atoms could react with CO_2 and reduce it to CO_2H . But reaction of OH radicals with trace amounts of CO present in CO_2 as impurity might also contribute to the formation of CO_2H radicals. For the mixture of CO and CO_2 on silica gel, both gases were adsorbed on the surface, so the sites available for CO adsorption would be decreased. Consequently, the total amounts of CO_2H radical formed would be lower than when CO alone was adsorbed on silica gel (Fig. 1).

The formation of HCO_2H from CO_2H radicals was demonstrated by the irradiation experiment at room temperature. After the CO_2H radicals had disappeared upon warming, re-irradiation of the silica gel sample at room temperature produced CO_2^- radicals. This same radical was also observed when authentic HCO_2H adsorbed on silica gel was irradiated at room temperature. Apparently, HCO_2H was formed during the thermal decay of CO_2H radicals, and irradiation at room temperature resulted in the photodecomposition of HCO_2H .

This study confirms the reports of Hubbard *et al.* that HCO_2H and possibly HCHO and other organic compounds were formed during the photolysis of atmospheric gases adsorbed on a simulated Martian surface, suggesting that these compounds may be formed on the surface of Mars as well. An important observation in this study is that these organic compounds were formed by the reaction of free radicals generated by the ultraviolet irradiation, with OH radicals playing a very important role. This observation is in contrast to the mechanism proposed by Hubbard *et al.*, who suggest that CO excitation is responsible for the organic synthesis. Our study suggests that photochemical synthesis of organic compounds could occur on Mars if the siliceous surface dust contains enough silanol groups and/or adsorbed H_2O , as bound water. Houck *et al.*¹⁸ recently provided high altitude infrared spectroscopic evidence that the wind-blown surface dust on Mars contains about 1% bound water by weight. The low partial pressure of CO in the Martian atmosphere probably would not pose serious problems to the organic synthesis since CO_2 , which is present in large quantity, also could react with H atoms to form CO_2H radicals. The effect of O_2 on these syntheses is minimum, since in our ex-

periment the addition of 1 mmHg of O_2 to the CO-CO_2 mixture adsorbed on silica gel showed little effect on the CO_2H radical yield (Fig. 1). We suggest that further study of such heterogeneous systems may provide a mechanistic basis for gauging the potential importance of gas-solid photochemistry for chemical evolution on other extraterrestrial bodies, on the primitive Earth, and on dust grains in the interstellar medium¹⁹.

We thank Drs Gaylord M. Androes, Edward C. Y. Inn, and Ronald F. Reinisch for discussions. Dr G. E. Voecks supplied the silica gel. S.-S. T is a National Research Council Research Associate.

Microearthquake survey of Median Valley of the Mid-Atlantic ridge at $36^{\circ}30'\text{N}$

MICROEARTHQUAKE activity in the median valley of the Mid-Atlantic Ridge near $36^{\circ}30'\text{N}$ has been monitored using expendable radio-sonobuoy arrays. Similar techniques have been used by Reid *et al.*¹ in the Gulf of California, Macdonald and Mudie² near the Galapagos spreading centre and recently by Reid and Macdonald³ near fracture zones A and B shown in Fig. 1 (ref. 4). This study provides area coverage not obtained by Reid and Macdonald whose experiment was confined to the fracture zone regions. A new method of sonobuoy position determination was used that provides relative buoy locations (locations with respect to each other) to within ± 10 m. The ultimate positioning capability in latitude and longitude depends on the accuracy of the primary navigation system available. Satellite navigation can yield absolute positions to within ± 100 m. An estimated actual accuracy of ± 200 m is ascribed to the experiments

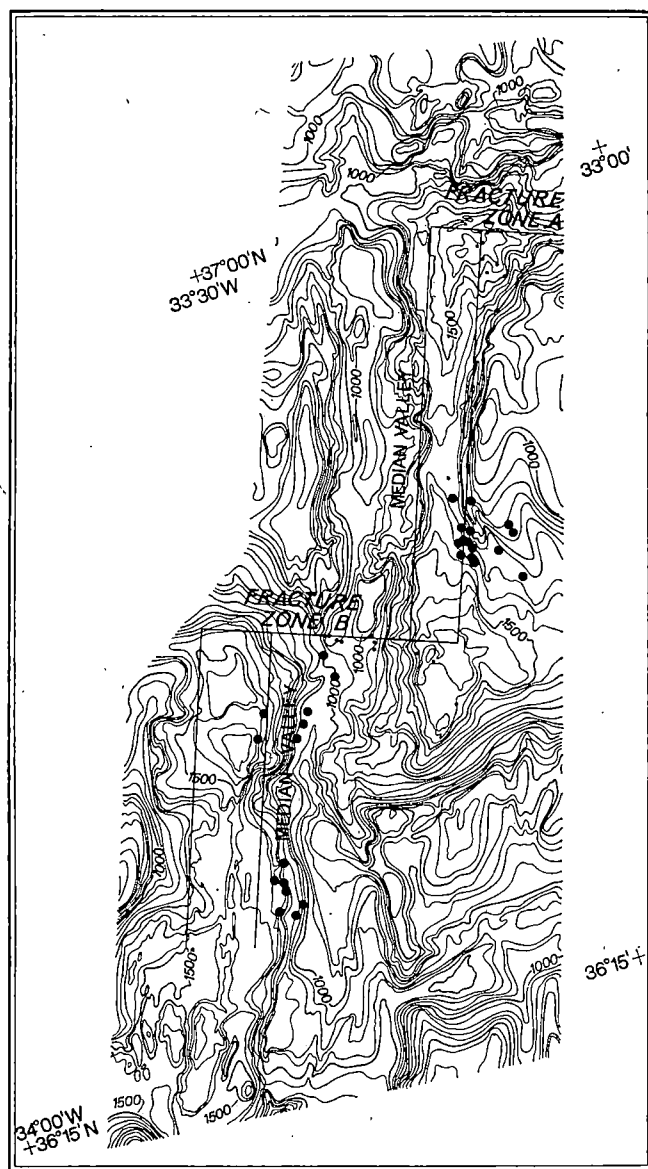

Fig. 1 Bathymetric map of part of the Mid-Atlantic Ridge. Epicentre locations obtained in this study are shown as large circles. Small circles represent epicentres determined by Reid and Macdonald³. Approximate location of fracture zones and median valley is shown. Contours are in uncorrected fathoms.

reported here. Accuracy of this order allows correlation of epicentre locations with topographic features of similar scale size. Recently acquired bathymetric data (K. C. Macdonald and colleagues, in preparation) indicate that significant features of the ridge near 36°30'N, such as transform faults and valley walls, can be defined by scale sizes of some hundreds of metres. A total of 112 events definitely attributable to seismic activity were recorded in 72 h of listening, yielding an average rate of occurrence of 1.5 events h^{-1} .

Arrays consisting of three US Navy AN/SSQ-57 calibrated sonobuoys, with 91.4-m hydrophone depth, were launched at three locations within the study area. The arrays approximated equilateral triangles with legs of 1.5 to 2 km. Sonobuoy positions were continuously monitored in real time by an acoustic navigation system originally designed to track the course of the submersible DSRV Alvin, but modified to track a moving hydrophone. The system uses either two or three bottom-moored acoustic transponders and a shipboard transmitter/receiver. (Two transponders make orientation with respect to the transponder baseline ambiguous; three transponders resolve the ambiguity. Often the ambiguity can be resolved from bathymetric data, or alternative navigation

aides, thus allowing the use of only two transponders.) Determination of the position of a sonobuoy consists of first measuring the round trip travel time of an acoustic pulse emitted by the ship, received and retransmitted at a different frequency by each transponder and received aboard ship. This observation provides the one way travel time from ship to transponder, t_1 . A second transmitted pulse is received by the transponders and retransmitted, but this time is received by the sonobuoy, thus determining the ship-transponder-sonobuoy acoustic travel time, t_2 . The travel time from transponders to buoy is $t_1 - t_2$. Slant ranges to the transponders are computed, corrections are made for sound velocity variation with depth (ray bending), and buoy position is resolved into a rectangular coordinate system whose origin is fixed with respect to the transponder net. Travel times can be determined to within 2 ms, thus establishing a limitation of about ± 3 m in buoy positioning. In practice a sonobuoy fix can be obtained every 20 to 30 s. (The maximum round-trip travel time range of the navigation system was about 12 s.) Absolute positioning of the transponder net in latitude and longitude is done using satellite fixes.

Seismic signals from the sonobuoy array elements were low pass filtered (0 to 500 Hz) and recorded on an f.m. analogue tape recorder with frequency response ± 0.7 dB from d.c. to 5 kHz. An example of three events received by a single sonobuoy within an interval of about 40 min is shown in Fig. 2. The event depicted in Fig. 2a occurred within the bounds of the triangular array, less than 1 km away from all sonobuoys. First compressional wave arrival (P) and two reflections of that wave through the water column (P_1 and P_2) are clearly shown. Shear waves (S) and direct water waves (T) are not evident because of the proximity of the event. Figures 2b and 2c are more distant and exhibit prominent T-phase arrivals. These figures give an indication of the excellent recording conditions encountered. Sea states were typically 0 to 1/2 with wind and swell near zero. Ambient noise levels at 25 Hz were chiefly less than -10 dB with respect to $1 \mu\text{bar}$. It is estimated that the array could detect microearthquakes of magnitude $M > -1$.

Power spectra of the events shown in Fig. 2 are shown in Fig. 3. These spectra have been corrected for the rising frequency response of the calibrated sonobuoys and represent an earthquake signal in excess of background noise. The spectra peak is about 15 to 25 Hz, rather greater than the typical peak frequencies of distant events⁵. This is not surprising since there is increased attenuation of high frequencies over long propagation paths. Measured peak pressures are

Fig. 2 Example of microearthquakes received with a single sonobuoy. Event a is less than 1 km horizontal range from the receiving hydrophone. a, 0231:30; b, 0156:40; c, 0154.

Fig. 3 Power spectra of three typical events (signal in excess of noise).

comparable to an equivalent source strength of some 75 to 100 dB relative to 1 μ bar at 1 m assuming spherical spreading over the entire transmission path.

Earthquake epicentre locations were determined by measuring the relative arrival times of the initial P wave on all three buoys. A horizontal, plane bottom was assumed, characterized by a compressional velocity of 5,000 ms^{-1} . When S-wave arrivals were distinct, S-P travel time differences were also used. The arrival times were solved iteratively for epicentre location using a computer. Geographical location accuracy is estimated to be within ± 200 m, the major sources of error being the estimate of absolute latitude and longitude of the transponder navigation net, the assumed crustal compressional velocity of 5,000 m s^{-1} and the assumption of zero focal depth^{3,6}.

Although 112 events were recorded, only 29 had sufficiently distinct arrival times to allow accurate epicentre location. The small array dimensions (restricted by the range of the acoustic navigation net) made it impossible to locate events more than about 20 km away from the array. Thus it is difficult to compare the level of seismicity in the median valley with that near transform faults because virtually all recording time was over median valley segments. Reid and Macdonald measured about 0.5 events h^{-1} on fracture zones A and B, while we measured 1.5 events h^{-1} , but their system was less sensitive because of poor weather conditions and higher ambient noise levels.

All but two of the located events occurred along the boundary between the median valley floor and the median valley wall. Near-bottom, bathymetric profiles in the vicinity of the median valley both north and south of fracture zone B show that the median valley walls are constructed predominantly of normal faults (K. C. Macdonald *et al.*, unpublished). Since the microearthquakes in this study cluster at the edges of the median valley and not along the axis, the tremors are probably associated with the incipient and ongoing uplift of fault blocks forming the wall rather than with the dynamics of intrusion in the centre of the median valley. Indeed, the events located occurred only along the eastern edge of the median valley where the east rift wall

begins, even though the array detection range was sufficient to detect events along the west wall and valley axis. This asymmetry is also apparent in the bathymetry and magnetics; the regional gradient of the rift walls is more gradual on the east side, and the axis of the central magnetic anomaly is offset several kilometres to the east (ref. 5 and H. D. Needham and F. Francheteau, to be published). Although our sampling is over a very short time interval, the seismicity distribution suggests that seafloor spreading activity here may be highly asymmetric, skewed towards the east at present.

This study was carried out as part of Project FAMOUS, during cruise 77 of RV Atlantis II in August 1973. We acknowledge the cooperation and assistance of W. B. Bryan, chief scientist of the cruise. This work was supported by a National Science Foundation grant and an Office of Naval Research contract.

Velocity ratios for rocks with oriented microcracks

THE velocity of sound in 55 gneisses from the Alps has been determined by Johnson and Wenk¹ in ambient conditions. Because of their foliated fabric, these rocks show a strong anisotropy in physical properties chiefly on account of preferentially oriented microcracks at the boundaries of mineral grains. Johnson and Wenk's determinations were made along the principal fabric directions, assuming orthorhombic symmetry; following their notation, the *c* direction is perpendicular to the foliation and therefore to the oriented microcracks, and the *a* and *b* directions lie within the plane of foliation. Along each direction of wave propagation, there are two shear velocities, corresponding to the two mutually perpendicular directions of polarisation parallel to the principal axes.

We analysed the data provided by Johnson and Wenk and found that, at 95% confidence interval, the mean values of the ratios between the velocities of the compressional waves and shear waves are: along the *a* direction, $\alpha_a/\beta_{ab} = 1.42 \pm 0.02$ and $\alpha_a/\beta_{ao} = 1.65 \pm 0.03$; along the *b* direction, $\alpha_b/\beta_{ba} = 1.59 \pm 0.02$ and $\alpha_b/\beta_{bo} = 1.77 \pm 0.03$; and along the *c* direction, $\alpha_c/\beta_{ca} = 1.29 \pm 0.02$ and $\alpha_c/\beta_{cb} = 1.26 \pm 0.02$. Thus there is distinctive anisotropy in the velocity ratios for the *a* and *b* directions where the polarisation of shear waves is either perpendicular or parallel to the foliation. On the other hand, along the *c* direction, where the polarised shear waves all lie within the plane of foliation, there is little anisotropy in the velocity ratio. A more interesting result is that the ratios for the *c* direction are very much

lower than those along the other directions, apparently because of the oriented microcracks perpendicular to the direction of wave propagation. These observations are in qualitative agreement with the theoretical prediction by Anderson *et al.*².

Surface energy calculations for muscovite

Muscovite, $\text{KAl}_2(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH})_2$, has cleavage properties which make it suitable for studying phenomena which occur on surfaces and interfaces. The excellent cleavage produces surfaces which will readhere with the same or nearly the same strength¹⁻³, and which can be molecularly smooth over large areas⁴. Experimental results indicate that the attraction across the (001) cleavage is greatest in a vacuum and becomes less in air or various other media, and there is evidence that the rate of cleavage influences the strength of attraction⁵.

Theoretical studies have been based on the assumption that electrostatic forces provide the major component of the interlayer attraction and this is supported by the observation that cleaving mica creates electrical charges on the cleavage surfaces. Computations depend on a knowledge of the arrangement of the atoms on the surface of the cleavage plane, known ionic charges, and the distances to ions on the other side of the cleavage plane. Splitting occurs along the plane containing the potassium ions, which are equally distributed on both new surfaces. This has been confirmed using Auger electron techniques⁶.

Earlier calculations have two major defects. First, information about the crystal structure has been based on an idealised arrangement of atoms and is therefore inaccurate. Second, electrostatic energy has either been calculated for pairs of charges on each side of the cleavage, or else a two-dimensional summation has been used.

In fact, the structure of muscovite is very different from the ideal structure. There is a considerable distortion from the ideal hexagonal arrangement of oxygen ions and the potassium ions have six coordinating oxygens rather than twelve⁷. Accurate refinements have culminated in a neutron diffraction study which located the hydrogen ions⁸.

FIG. 1 A plot of the electrostatic energy (●, right axis) and Madelung number (▲, left axis) against the amount of split across the (100) face of NaCl.

FIG. 2 A plot of electrostatic energy against the increase in the interlayer region between the aluminosilicate layers of muscovite. Curve *a* refers to the case in which the K ions remain in a plane equidistant from the two neighbouring mica layers; curve *b* is the case in which all the K ions remain on one layer and curve *c* represents an ordered arrangement with half of the K ions on each layer.

Electrostatic forces act over long distances and a correct calculation should take into account all of the atoms in the structure, and not just those on the cleavage surface. The surface energy represents the energy difference between a single crystal and one which has been separated into two parts across a plane. We have calculated the electrostatic energy of the normal crystal and of a series of structures which have an increased distance between atoms on either side of the plane. As the distance across the plane increases, the electrostatic energy approaches the energy for an infinite separation. These values give the surface energy directly.

As an example, the surface energy for the (100) face of NaCl has been calculated. The electrostatic energies of the normal and expanded structures were obtained using a computer program¹⁰. Figure 1 shows the Madelung number (left side) and the electrostatic energy (right side) against the increase in distance across the (100) face (horizontal axis). The Madelung number and electrostatic energy rapidly approach 1.68231 and $-196.87 \text{ kcalorie mol}^{-1}$ respectively, corresponding to a surface Madelung number of 0.06525 and a surface energy of $7.63 \text{ kcalorie mol}^{-1}$. These are in excellent agreement with earlier results¹¹.

The results of similar three dimensional calculations for the (001) plane of muscovite, based on the refinement of Rothbauer are shown in Fig. 2. Three distributions of interlayer potassium resulted in the three curves: curve *a* is for a structure in which the potassium ions remain in a plane equidistant from both neighboring layers; curve *b* is the case in which all of the potassium ions remain on one cleavage surface; curve *c* is for an ordered array of half of the potassium ions on each surface. Model *a* is clearly an unrealistic structure. This is evident from the energy plot which shows the greatest energy input required for cleavage. Model *b* is also energetically unfavourable but may represent the situation locally on a cleavage surface. Model *c* is the ordered array generated when the potassium ions at $z = \frac{1}{4}$ and $\frac{3}{4}$ are split so that two ions normally related by the c-face centring become crystallographically independent and remain on opposing surfaces. It is clear that for the ordered array, the electrostatic energy rapidly assumes a constant value which is the energy of an isolated mica layer. The energy difference between the normal and 'cleaved' mica is $0.098 \text{ e}^2 \text{ Å}^{-1}$ ($32 \text{ kcalorie mol}^{-1}$, 891 mJ m^{-2}).

The behaviour of the three models can be understood by considering the expression for the electrostatic energy:

$$\frac{-e^2}{2} \sum_{r=1}^{\infty} \sum_{s=1}^N \frac{Z_r Z_s}{R_{rs}}$$

where e is the charge on the electron, Z is the ionic charge

in one of the atoms in the structure, N is the number of atoms in the unit cell and R is the interionic distance. The arrangement of ions in model a is such that as the layers separate, the K^+-K^+ interactions remain constant while the K^+-O^- interactions decrease. The result is a decrease in the electrostatic energy. Model b is similar but there are fewer K^+-O^- interactions which become smaller. The K^+-O^- interactions in model c change as in model b , but many of the K^+-K^+ interactions decrease.

The surface energy of muscovite in a very high vacuum (1×10^{-13} torr) is about $5,000 \text{ mJ m}^{-2}$ ($168 \text{ kcal mol}^{-1}$, $0.05 \text{ e}^2 \text{ \AA}^{-1}$) (ref. 3). This large value implies that the potassium ions in real crystals are not ordered, and the energy-separation curve will lie between curves b and c (Fig. 2). In addition, if there is a high rate of splitting, the chances of maintaining locally ordered regions of potassium will be less than if the rate is low. A crystal which has been rapidly split would have an experimental curve closer to b than would a crystal split more slowly. This is in agreement with the observation that more energy is required to cleave mica rapidly⁵. It is not sufficient to assume that an average of half of the potassium will be on each cleavage surface; the arrangement of the potassium ions on the surface is an important factor in determining the interlayer attraction.

I thank Drs A. Bailey and S. Weller for their useful comments. The research was supported in part by a grant from the Air Force Cambridge Research Laboratory.

New calcium silicate phase in hydrothermally treated γ -dicalcium silicate-quartz mixtures

HYDROTHERMALLY treated γ -dicalcium silicate-quartz mixtures have been investigated by several authors as a potential calcium silicate building product which, because of its low water content, could be used as refractory or heat insulating material. The phase composition of material formed at 150–600° C and 5–300 bar, for bulk molar Ca/Si ratios between 3.0 and 1.5 has been determined by Speakman *et al.*¹. Jernejčič *et al.*^{2,3} investigated lower Ca/Si molar ratios, that is, between 1.5 and 0.5 at 180–250° C, under saturated and superheated steam conditions. Superheated steam conditions during the initial period of hydrothermal reaction gave an unknown phase with a strongly pronounced diffraction maximum of 3.15 Å in the multiphase reaction products for bulk Ca/Si ratios lower than 1.25. Using previously recorded crystallographic data for calcium silicates and calcium silicate

hydrates, the maximum of about 3.15 Å could be assigned to the gyrolite group of hydrates. These phases, however, exhibit strong basal reflections at 22 and 19 Å. These basal reflection were not observed and identification was therefore necessary, particularly because there were no signs of pseudowollastonite in samples heated to 1000° C, as should have been the case if gyrolite or truscotite or a mixture of both were originally present.

To study the silicate structure of the 3.15 Å phase, the samples were treated with 0.1 M HCl and afterwards analysed by X-ray diffraction. The patterns obtained after acid treatment showed that the 3.15 Å phase remained even when all the coexisting xonotlite had been destroyed. This observation suggests that the silicate anions in the 3.15 Å phase are relatively highly condensed. Although the samples investigated varied in their starting Ca/Si ratio and in the original phase composition, all gave the same pattern after acid treatment. It was therefore obvious that the pattern belonged to one and the same phase. Table 1 gives this pattern.

To index reflections for the 3.15 Å phase the unit cell parameters and symmetry were found by selected area electron diffraction. Microscopic observation of samples rich in the 3.15 Å phase showed lath-like oriented aggregates. Near the zero setting of the goniometer most of the particles gave a characteristic electron diffraction pattern (Fig. 1). To ensure reliable measurements of values of d^* from this pattern the 2.338 Å powder ring of aluminum was used as internal standard; this gave 11.8 and $3.7 \text{ \AA} \pm 1\%$ for the two perpendicular repeat distances. The crystals are elongated parallel to the 3.7 Å direction, which was chosen as b . The repeat distances are similar to the parameters a and $b/2$ for tobermorite, but the general features of the tobermorite (001) electron diffraction pattern are quite different from that of the 3.15 Å phase. Whereas tobermorite shows marked pseudohalving of a and b , and only those reflections which $h + k = 2n$ (for the pseudocell), the 3.15 Å phase shows a primitive (001) reciprocal lattice section. The two phases also differ in c . The third row spacing of the reciprocal lattice for the 3.15 Å phase was derived from series of electron diffraction patterns obtained by tilting crystals about a ; this gave $c = 7.0 \text{ \AA}$. The electron diffraction patterns contained streaks that showed true b and c to be double those determined from the strong reflections only. The repeat distance of 7.4 Å in the b direction indicates that the silicate part of the structure consists of disordered dreierketten. The streaks of strong intensity, which were observed for $k + l = 2n$, indicate that the suffix $A \propto 22$ for the reciprocal lattice of the 3.15 Å phase. There are also, however, weak streaks for $k + l = 2n + 1$, so the true suffix should be $P \propto 22$ (ref 4). Electron diffraction patterns obtained by tilting

FIG. 1 Characteristic selected area electron diffraction pattern of 3.15 Å phase (corresponding to (001) reciprocal lattice section).

crystals about a^* and b^* also showed that the phase is monoclinic.

Using the unit cell parameters approximately determined from electron diffraction patterns it was possible to index all the reflections appearing on the X-ray diffraction pattern (Table 1). The unit cell parameters refined from the X-ray data are: $a = 12.02$ Å, $b = 7.42$ Å, $c = 14.14$ Å and $\beta = 98^\circ$. As already mentioned, the value of b indicates that silicate chains, similar to those existing in compounds of the wollastonite type are present in the 3.15 Å phase; consistent with this indication the 3.15 Å phase transforms into β -wollastonite at 700° C. The phase transition brought about by thermal treatment was followed on the sample richest in the 3.15 Å phase; it also contained unreacted quartz and a little xonotlite. On heating the sample to 680° C the X-ray pattern of the 3.15 Å phase did not change markedly. In a sample treated at 700° C, β -wollastonite and quartz were the only phases identified. The sample containing the highest proportion of the 3.15 Å phase was also used to evaluate approximately the Ca/Si molar ratio of the phase. Calculations using the weight fraction of unreacted quartz determined by X-ray diffraction and the loss on ignition gave a molar Ca/Si = 0.84. The ratio was also determined by electron microprobe, using a Philips EM300 electron microscope and an energy dispersive X-ray analysis system; after applying corrections⁵ an average molar ratio of 0.81 ± 0.03 was obtained. The amount of structurally important water in the 3.15 Å phase has not yet been precisely determined, but according to differential thermal analysis, thermal gravimetry and differential thermal gravimetry measurements it must be low (about 1%). Further work on the exact determination of the water content and the possible arrangement of atoms in the 3.15 Å phase is in progress.

This work is supported by the Cement and Asbestos-cement Industry, Saloniit Anhovo. The first information on the 3.15 Å phase we reported at the Third International Symposium on Calcium Silicate Building Products, Utrecht, September 1973.

New method of nucleating diamonds

SYNTHESIS of diamond from graphite in the size range <0.1 to 1 mm requires an ultra-autoclave capable of operating at about 100,000 atm and 2000° K (ref. 1). A molten metal solvent-catalyst is also needed so that the conversion may be achieved in a relatively short time (minutes). Catalysts used include chromium, manganese and tantalum plus all elements of Group VIII of the periodic table, but nickel is used most frequently. The cross hatched region of Fig. 1 shows the combinations of pressure and temperature used for diamond synthesis when nickel is the catalyst.

It is advantageous to use metal-coated diamonds in resin-bonded wheels when grinding relatively ductile materials such as cemented tungsten carbides or hard tool steels. Nickel coated grains are most commonly used for wet grinding and about 55% of the weight of diamond is deposited as nickel which corresponds to a 15% increase in volume or an increase in diameter of about 15%. The metal coating is believed not only to provide a larger area for bonding but also promote heat transfer away from the wheel surface and to retain particles in the wheel face when grains fracture due to mechanical shock or thermal fatigue.

As well as these thermal and mechanical influences the metal coating could act to decrease wear by a chemical mechanism. At atmospheric pressure diamond represents an unstable form of carbon which will tend to transform to graphite if the temperature is sufficiently high and the soft transformed graphite will be rapidly worn away. A very thin coating of nickel will smear over the surface of an active coated diamond grain and in so doing could alter the

FIG. 1 Diamond-graphite equilibrium diagram with the diamond-growing region (using a nickel catalyst) shown cross hatched (ref. 2).

Fig. 2 a, Single-point cutting arrangement; b, tip of worn tungsten carbide sphere.

rate of wear by changing the equilibrium between the conversion of diamond to graphite and the conversion of graphite to carbon. Local conditions at the tip of the abrasive grain will be in the range of those found in the apparatus used to synthesize diamond from graphite in the presence of nickel.

When grinding steel, surface temperatures estimated as $\sim 3000^\circ\text{C}$ are obtained³ with grain-chip contact pressures as high as 2×10^6 pounds inch⁻² (130 katm)⁴. This condition marked by a cross on Fig. 1 is seen to exceed somewhat the range of operation of that used in diamond synthesis (cross hatched region). It is to be expected that under such extreme conditions the diamond nuclei produced will be extremely small, closely spaced and spontaneously formed.

The extreme conditions found at the tip of a cutting tool have been used previously to promote chemical reactions in organic synthesis in the process known as mechanical activation⁵. The very high temperatures and pressures existing at the tool tip constitute autoclave conditions without the need for an actual autoclave. This, together with the unique cleanliness of the nascent surfaces generated, causes an immediate reaction which is of great importance for organometallic reactions that are autocatalytic, such as those of the Grignard type.

To test the feasibility of generating diamond nuclei at the tip of an abrasive grain we conducted the following experiment. A tungsten carbide sphere, 1.5 mm in diameter, was coated with layers of nickel and graphite. The tungsten carbide sphere was first cleaned by sputter etching and then three thin layers were deposited in the order nickel-carbon-nickel using a sequential sputtering apparatus.

The coated tungsten carbide sphere was then cemented into a hollow head screw which in turn was threaded radially into the surface of an aluminum disk 8 inches (20 cm) in diameter. The disk was mounted on the spindle of a surface grinding machine in place of the usual grinding wheel and used to cut a groove in a piece of hardened ball bearing steel (AISI52100 steel of hardness R_c61) as shown schematically in Fig. 2. The speed of the disk (V) was in the range of conventional grinding (6,000 feet min⁻¹ or 30 m s^{-1}) while the table speed (v) and depth of cut (d) were adjusted to provide individual chips comparable in size to those in ordinary surface grinding ($v = 6\text{ inch min}^{-1}$ or 2.54 mm s^{-1} and $d = 0.001\text{ inches}$ or $25\text{ }\mu\text{m}$). The length of groove produced was 0.5 inches (12.5 mm) which corresponds to 250 individual cuts.

After cutting, a small flat was found on the tip of the tungsten carbide sphere (Fig. 2b). When the worn surface of the composite coating was examined in a scanning electron microscope for evidence of diamond nuclei from direction A in Fig. 2a, many small nucleation sites about $1\text{ }\mu\text{m}$ in diameter were evident at the inner nickel layer (Fig. 3a). The nuclei shown in Fig. 3a are believed to be diamond nuclei generated under the extreme conditions of temperature and pressure pertaining during cutting. Figure 3b shows a similar scanning electron micrograph of the composite surface abraded by hand on fine abrasive paper (4/0 silicon carbide) at low speed. In this case the abraded specimen is subjected to relatively low temperature, and hence conditions are not

favourable for the formation of diamond. The nuclei evident in Fig. 3a are not present in this case.

We used the Debye-Scherrer X-ray diffraction technique in an attempt to verify that the nuclei evident in Fig. 3a were in fact diamond. The sample was held stationary in the camera with the X-ray beam aimed at the wear scar. Tungsten carbide, titanium carbide and nickel patterns were clearly evident. In addition, one spot (corresponding to the strongest diamond line) was also found, possibly indicating the presence of diamond. The small concentration of nuclei makes it very difficult to obtain certain verification of their structure but work is continuing on this problem.

The practical implications of the possibility of generating diamond nuclei at the tip of an abrasive grain seem to lie in at least three areas:

- (1) The rate of wear of diamond grinding wheels could be reduced;
- (2) A source of diamond seeds for epitaxial growth of diamond by vapour phase deposition of diamond would be opened up;
- (3) It would provide a convenient method of studying the formation of new high temperature, high pressure stable phases of materials.

Some of the graphite formed by degradation of diamond during wear may be reconverted to diamond if nickel is present. The presence of nickel would thus alter the net rate of conversion of diamond to graphite. If so, it should be advantageous to provide a source of graphite to the diamond grain tip in addition to that coming from the conversion of diamond.

A diamond phonograph stylus might be made by coating an aluminum oxide cone of proper geometry with alternate layers of nickel and graphite. By making a few cuts in each of several directions seeds would be generated on the surface which could then be enlarged and subsequently grown together by epitaxial growth. The result would be a relatively large item of inexpensive material coated with a thin layer of diamond in the critical region only.

Although there is some evidence for the nucleation of diamonds by the technique reported here, it is not completely conclusive. But since the method is novel, simple and inexpensive, it could lead to many new important applications similar to those presented here. More important, if this

Fig. 3 a, Scanning electron micrograph of portion of inner nickel layer showing many (possibly diamond) nuclei; b, scanning electron micrograph of inner nickel layer abraded by hand at low speed. No nuclei seem to be present in this case. I, Tungsten carbide sphere; II, inner nickel layer; III, carbon layer.

mechanism is operating in grinding with diamond abrasive, it sheds light on the basic wear mechanism and suggests means for reducing the rate of wear in practice.

We thank Dr Sidney S. Pollack for carrying out the X-ray analysis.

Late Pleistocene desiccation along the White Nile

MORE than a century ago Baker¹ described the Blue Nile as a mountain stream, rising and falling with great rapidity, and the White Nile as a river of lake origin, flowing through vast treeless swamps in a land of "malaria, marshes, mosquitoes, misery". Three decades later Hull² noted that the flow of the main Nile had once been greater, and early this century a controversy arose which persists to this day. Was Nile discharge greater during the glacial periods of Europe and East Africa? Or were the glaciations coeval with tropical aridity?

Hume and Craig³ maintained that glacial ice caps in East Africa would displace the monsoon winds southwards, reducing precipitation over Ethiopia and thereby curtailing the flow of the Sobat, Blue Nile and Atbara, which currently account for more than 90% of the main Nile flood. Penck⁴ considered that when the northern Sahara was wet the southern Sahara was dry and encroached farther south. During a glacial period the arid belt lay 5° nearer the equator as a result of lower global temperatures and weakened atmospheric circulation.

More recently Fairbridge^{5,6} has equated Nile aggradation with diminished discharge during glacials, arguing that, since the Nile is now well able to transport its load to the delta, widespread silt deposition above the first cataract must imply reduced competence. Theoretical reconstructions of full glacial climates^{7,8} posit drier climates in areas as far afield as the south-west United States⁹, south-east Australia¹⁰, and parts of the Mediterranean littoral¹¹. In essence, lower temperatures imply lower evaporation rates⁷, which should result in lower rainfall^{5,7}.

Since 1960 many workers have reported evidence which seems to oppose the glacial aridity model and to favour the view that Nile discharge was greater than now during much of the late Pleistocene. Butzer and Hansen¹² referred to "revolutionary changes" in the late Pleistocene hydrographic regime of the Nile, and concluded that the wetter phases were synchronous in both Ethiopia and Egypt, except during deposition of the Masmas Formation at Kom Ombo about 20,000 yr BP. De Heinzelin^{13,14} also equated wadi activity in Nubia with higher rainfall in Ethiopia, Nile aggradation coinciding with conditions of maximum flow. Wendorf and Said¹⁵ described a phase of rising Nile level and widespread silt deposition in Nubia from 20,000 to 12,000 yr BP; and Wendorf and colleagues¹⁶ have distinguished three aggradational phases in Nubia between 16,000 and 12,000 yr BP, which were coeval with aridity in that region.

Three contradictory palaeoclimatic models purport to explain late Pleistocene aggradation by the main Nile. One equates aggradation with reduced Nile discharge and glacial aridity in Ethiopia^{5,6}. The second equates aridity with river incision, and greater Nile discharge with aggradation and wetter conditions in Nubia^{12,13}. The third equates siltation with high Nile levels and local aridity¹⁶. To resolve these issues the White Nile and the Blue Nile require separate study. We now present evidence which suggests that the White Nile had a much reduced and highly seasonal flow during the late Pleistocene before it rose to several metres above its modern unregulated flood level between 12,000 and 8,000 yr BP.

During a survey of prehistoric sites along the White Nile in January-March 1973 in association with J. D. Clark and an archaeological team from Berkeley, we collected microcrystalline dolomite and calcite from beneath subfossil freshwater shells which were laid down between 11,000 and 11,500 yr BP. When the shells were deposited, the White Nile flood level was 378 m, which is 5 m above the mean minimum and 2.5 m above the mean maximum water level¹⁹ at Esh Shawla before the Jebel Aulia dam was built (Fig. 1). The carbonate came from a depth of 3.75–3.90 m at site 2B and of 4.0–4.8 m at site 2. Above the carbonate was a layer of grey to yellow fluviatile sand from 0.5 to 1.1 m thick, locally with a basal admixture of clay and coarse quartz sand (Fig. 2).

An almost horizontal layer of greyish green lacustrine clay capped the sand and extended about 13 km west of the present White Nile to near Jebel et Tomat in latitude 13°36'N. The green clay was up to 1.5 m thick, with a surface elevation of 377.8 m in the west rising imperceptibly to 379.5 m some 7 km further east. Immediately above the green clay was a discontinuous shell-bed generally 5–10 cm thick made up of unbroken freshwater shells of *Cleopatra bulimoides* (Oliv.), *Melanoides tuberculata* (Müller) cf.

TABLE 1 Carbon-14 ages of shells in sediments bordering the White Nile

Site	Sample	Depth (m)	Elevation of base of shell beds (m)	Location	Age (yr BP)	Remarks
1	I 1486	1.45–1.70	377.3	13°35'N 32°41'E	11,300 ± 400	High river level ¹⁷
2	SUA-75	1.2–1.4	377.3	13°36'N 32°40'E	11,250 ± 220	High river level
3	I 1485	1.8–1.9	376.5	13°56'N 32°22'E	8,370 ± 350	High river level ¹⁷
3	SUA-68	1.2–1.4	377.0	13°56'N 32°32'E	8,130 ± 225	High river level
4	SUA-72	0.3–0.45	~398	15°23'N 32°22'E	8,400 ± 150	Local lakes full
4	SUA-74	0.45–0.60	~398	15°23'N 32°22'E	7,620 ± 130	Local lakes full

11	SUA-215B	Modern		White Nile	152.6% modern	Modern <i>Pila wernei</i> shell

Unless specified, all dates are from the Radiocarbon Laboratory, University of Sydney.

dautzenbergi Pilsbry and Bequaert, *Corbicula africana* (Krauss) and *Biomphalaria sudanica* (Martens). At site 2, fish spines and vertebrae were mixed among the shells, which gave a ^{14}C age of $11,350 \pm 220$ yr BP, in close agreement with the age of $11,300 \pm 400$ obtained from site 1^{17,20} (Table 1). Above the shell bed was a dark, cracking clay up to a metre or more thick, which accumulated in swamps left by the receding White Nile. Between about 12,000 and 8,000 yr BP, the White Nile remained high and formed an extensive lake up to 30 km or more wide (site 3, Table 1). Small lakes also existed west of the White Nile some 20 km north-west of Jebel Aulia (sites 4 to 6) between about 8,500 and 7,000 yr BP²¹, after which they remained quite dry.

Geochemical and palynological evidence indicate that between >14,500 and 12,000 yr BP Lake Victoria had no outlet²², the regional climate was dry, and dry forest grew on Ruwenzori²³. The White Nile was deprived of water from the Uganda lakes, so that its flow dwindled to a mere seasonal trickle. Dune formation was active along both banks of the White Nile between Kosti and El Geteina^{24,25} (Fig. 1) and deposits of very pure carbonate accumulated in or along the river, which contained abundant calcium and magnesium, indicative of the high salinity concentrations brought about by increasing evaporation downstream—a feature of modern rivers in arid areas²⁶. Site 2B contained both dolomite and calcite crystals, suggesting that when the dolomite was form-

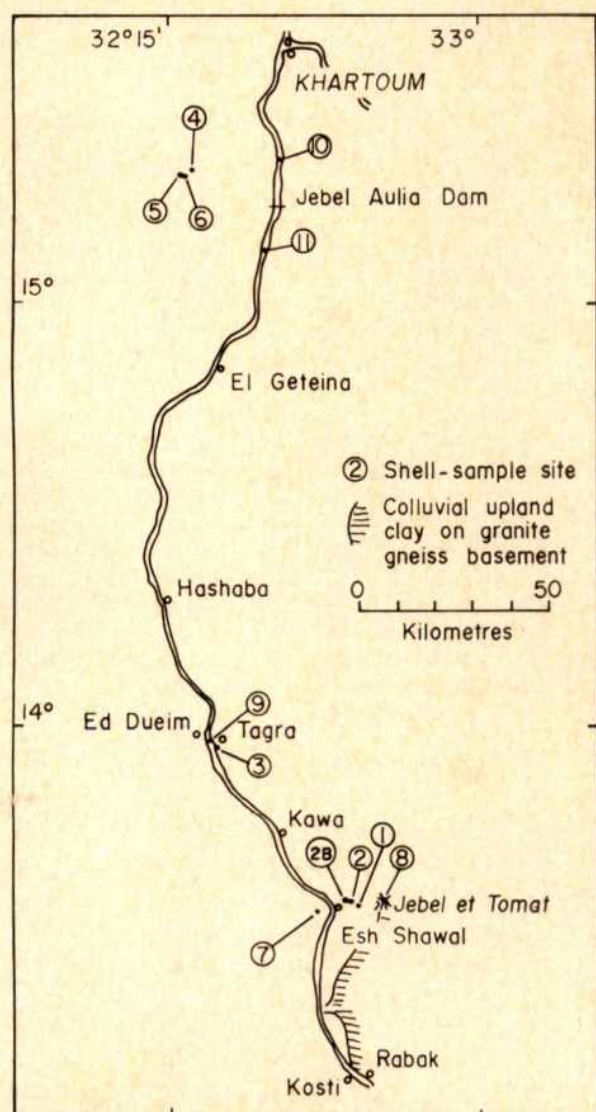

Fig. 1 Location of dated shell beds along the White Nile.

Fig. 2 Esh Shawal, section 2B.

ing magnesium-rich calcite was already abundant, and the ratio of dissolved Mg to Ca was at least 7 (ref. 27). It is worth noting that the levels of Lake Chad²⁸, Lake Rudol²⁹ and Lake Nakuru³⁰ were also very low at this time, and dunes were active in now vegetated parts of Nigeria³¹.

About 12,000 yr BP Lake Victoria overflowed, the level of the White Nile rose, and the dunes between Kosti and Ed Dueim became partly buried by alluvial clay. After 8,000 yr BP the level of the White Nile fell, dark clays accumulated in the swamps bordering the river until about 4,000 yr BP (Table 1, site 8), after which Neolithic man and increasing climatic desiccation accelerated the trend towards semi-desert conditions. The fixed dunes of Kordofan and the even flow of the modern White Nile indicate that the late Pleistocene dry period was more arid than the present semi-arid climate of central Sudan, and it is possible that the White Nile may have ceased to flow into the main Nile, which would thus have been even more seasonal in its regime than now.

We thank Richard Gillespie for the radiocarbon dates, Ruth Mawson and Dr John Talent for mollusc identifications and Dr Pat Conaghan for carbonate identifications.

BIOLOGICAL SCIENCES

Non-specific 'pairing' of DNA molecules by recombination enzyme of *Bacillus subtilis*

ATP-dependent deoxyribonuclease(s) (ATP-DNase) is involved in the genetic recombination process in *Escherichia coli*¹⁻³, *Diplococcus pneumoniae*⁴ and *Bacillus subtilis*⁵ and may also play an important part in DNA repair⁶⁻⁸, DNA replication⁹ and cell growth¹⁰. ATP-dependent or ATP-stimulated DNases have also been isolated and characterised in other microorganisms¹¹⁻¹⁴. We reported the purification and properties of this enzyme in *B. subtilis*^{15,16} and noted that at the 600-fold purification level, the enzyme requires ATP for the hydrolysis of double stranded (ds) DNA, but not for single stranded (ss) DNA¹⁶. Since the activities on ds and ssDNA appear to reside in the same enzyme, we suggested the possibility that ATP consumption is somehow linked to the active unwinding of dsDNA before the DNase can hydrolyse phosphodiester bonds¹⁶. Recently, Friedman and Smith²⁴ have also proposed an active role of ATP in dsDNA unwinding by *Haemophilus influenzae* enzyme, which is based on the structural feature of intermediate product DNA. To examine this possibility further, we tried to visual-

FIG. 1 Electron microscopic study of ATP-DNase-DNA complex: control. The reaction mixture (50 μ l) with 0.5 mM ATP was incubated at 0° C for 2 min and at 32° C for 3 min without enzyme. $\times 37,254$.

ize the unwound portion of DNA and the DNA-enzyme complex by electron microscopy. Although the visual evidence is still ambiguous, an unexpected observation has been made. We report here the unusual property of *B. subtilis* ATP-DNase which apparently brings DNA molecules into close proximity or causes non-specific 'pairing' of dsDNA molecules.

ATP-dependent DNase was purified from *B. subtilis* sonicate as reported previously¹⁶. The sonicate of cells was centrifuged at 40,000g for 20 min. The supernatant was further centrifuged at 100,000g for 90 min, followed by streptomycin sulphate and ammonium sulphate fractionations. The fraction between 40 and 60% saturation of ammonium sulphate was further fractionated by agarose column (A 5m, Bio-Rad Laboratories) and DEAE-cellulose column chromatography. The DEAE-cellulose purified enzyme (600-fold purified) will be called here Fraction VI enzyme in conformity with the previous paper¹⁶. This enzyme was purified

FIG. 2 Electron microscopic study of ATP-DNase-DNA complex. The reaction mixture (50 μ l) with ATP (0.5 mM) and one unit of Fraction VI enzyme (5.2 μ g protein). Incubation was for 2 min at 32° C. $\times 52,500$.

by glycerol gradient centrifugation to a final purity of approximately 5,000-fold. This latter enzyme preparation is called Fraction VIII.

The activity of ATP-DNase was measured by the release of acid-soluble DNA fragments from tritiated *B. subtilis* DNA. The DNA was phenol-purified according to the procedure of Saito and Miura¹⁷. Unless otherwise noted, the 'standard reaction mixture' (0.5 ml) contained the following: 25 mM Tris-maleate buffer (pH 7.5), 7 mM MgCl₂, 6 mM 2-mercaptoethanol, 0.5 mM ATP, 30 μ M nucleotide equivalent tritiated DNA, and 1–5 units of enzyme. One unit of enzyme activity hydrolyses 1 nmol of DNA nucleotide during 30 min incubation at 32° C.

The electron microscopic study of ATP-DNase on dsDNA was carried out as follows. Unless otherwise indicated, reaction mixtures contained the same components as the standard reaction mixture in the same concentrations except that the total volume was reduced to 50 μ l and 0.14 μ g of non-labelled phage λ DNA was used. Routinely a reaction was terminated by adding glutaraldehyde to the concentration of 10 mM at 0° C. The sample was kept for at least 10 min at 0° C and an aliquot was diluted with 0.01 M Tris-HCl, 0.001 M EDTA buffer, pH 9.0, to give 0.5 to 1 μ g ml⁻¹ DNA. Formamide and cytochrome *c* were added to final concentrations of 50% (v/v) and 0.01%, respectively. The sample was mixed thoroughly, and a few drops were spread on a water surface. DNA was picked up on carbon coated formvar grids. The sample was stained for 30 s in 0.001% solution of uranyl chloride in ethanol, washed briefly in 100% ethanol and air dried. Samples were shadow-casted with 80% Pt:20% Pd in a Denton DV52 vacuum evaporator and observed in a Phillips 300 electron microscope.

Phage λ DNA molecules incubated without enzyme in the presence of ATP and glutaraldehyde (control) were well spread and the majority of the molecules could be traced from

Fig. 3 Electron microscopic study of ATP-DNase-DNA complex. The reaction mixture (50 μ l) with ATP (0.5 mM) and 5 units of Fraction VI enzyme. Incubation was as in Fig. 2. $\times 60,000$.

end to end (Fig. 1). The control in the absence of ATP and glutaraldehyde showed similar pictures. When ATP-DNase of Fraction VI was present in the reaction mixture, however,

Fig. 4 Electron microscopic study of ATP-DNase-DNA complex. The reaction mixture (50 μ l) with ATP (0.5 mM) and one unit of Fraction VIII enzyme (0.7 μ g protein). Samples with one unit of enzyme purified on a glycerol gradient (Fraction VIII) were prepared and examined according to the procedure described in the text. $\times 64,220$.

a large portion of each DNA molecule was closely lined or 'paired' (non-sequence-specific pairing) (Fig. 2). Similar 'pairing' was also observed when ATP was withheld from the reaction mixture. Thus, omission of ATP from the reaction mixture in the presence of the enzyme did not significantly change the degree of 'pairing'. The degree of non-specific pairing was clearly dependent on the enzyme concentration in the reaction mixture (compare Figs. 2 and 3). In separate experiments, we have examined samples incubated with serially diluted enzyme (Fractions VI and VIII) in the electron microscope. The results showed that as the concentration of enzyme was reduced, the degree of 'pairing' also decreased. To try to eliminate the possibility that the non-specific pairing of DNA observed may be caused by some other contaminating proteins in the preparation, similar experiments to those described above using 600-fold purified enzyme (Fraction VI) were carried out using the same number of activity units of the 5000-fold purified enzyme (Fraction VIII). Figure 4 shows essentially the same degree of 'pairing' as that obtained using Fraction VI. In this case, also, omission of ATP gave a similar degree of 'pairing'.

Since the molecular weight of ATP-DNase of *B. subtilis* is estimated by sedimentation to be approximately 260,000, and since the enzyme purified on the glycerol gradient is fairly homogeneous (Ohi, Donovan and Sueoka, unpublished data), the reaction mixture of Fig. 4 contains approximately 1.5×10^{12} enzyme molecules and 2.5×10^9 molecules of λ DNA. If we assume that all enzyme molecules bind to DNA under this condition and also bind at random (for example, in a non-cooperative fashion) the average distance between enzymes would be 80 base pairs.

Other proteins, however, might cause similar non-specific pairing of DNA molecules as a result of cross-linking caused by glutaraldehyde fixation. Under our experimental conditions, addition of lysozyme to the reaction mixture in concentrations up to 500 μ g ml⁻¹ in place of ATP-DNase did not promote the non-specific pairing of phage λ DNA. In this respect, it should be noted that the reaction mixture contained 104 μ g ml⁻¹ (Fig. 2) and 520 μ g ml⁻¹ (Fig. 3) protein with Fraction VI enzyme and 14 μ g ml⁻¹ protein with Fraction VIII. Furthermore, various proteins have been reported not to cause such an effect on DNA: T4 gene 32 protein,

FIG. 5 Three basic configurations of dsDNA to dsDNA 'pairing'. The solid line represents double-helical DNA and the shaded area indicates pairing. The various configurations in Fig. 3 can be explained by combinations of these basic configurations.

RNA polymerase²⁰, cytochrome *c*, trypsin, chymotrypsin, dipropylfluorophosphate-treated trypsin and chymotrypsin, RNase, methylated-albumin, and lysozyme²¹.

Winder and Sastry²² reported that ATP-DNase of *Micrococcus smegmatis* formed a long-lived enzyme-DNA complex which could be trapped on the Millipore filter and assayed for its activity. Shemyakin *et al.*²³ also demonstrated the formation of the *B. subtilis* enzyme-DNA complex by glycerol gradient centrifugation. In separate experiments we have confirmed the existence of the enzyme-DNA complex by the Millipore filter method. These observations indicate that the ATP-DNase can form a stable complex with DNA. There are two possible modes of binding of the enzyme to DNA: one which enables the DNase to work in unwinding and hydrolysis, and one which causes the non-specific 'pairing' of DNA molecules.

From the present study, the detailed structure of the 'pairing' cannot be specified. The distance between the paired dsDNAs cannot be defined. DNA in Fig. 3 (high enzyme concentration) shows tight pairing, while DNA in other figures with 1/5 enzyme shows rather loose pairing. The difference may come from a higher resistance in the former preparation to stretching during the spreading with cytochrome *c*.

There has been no evidence of strand opening in any of the preparations we have looked at so far. This is not surprising since any strand separation should quickly be followed by annealing. All features of pairing in Fig. 3 can be accounted for by the three basic configurations schematically shown in Fig. 5 without introducing strand opening of double-stranded DNA. It is also clear that the 'pairing' is not limited to two dsDNAs. The sticking of more than two dsDNAs is seen in Fig. 3.

In conclusion, we have found that the ATP-DNase of *B. subtilis* brings DNA molecules into close proximity. We do not know at present the functional meaning of this 'pairing' nor its physicochemical basis. Since the enzyme is involved

in genetic recombination, however this property of the enzyme may have some significance in the mechanism of recombination and some other types of DNA-DNA interactions *in vivo*.

Zinc ions inhibit replication of rhinoviruses

THE rhinoviruses comprise a subgroup of the picornaviruses, distinguished by their acid lability. They are medically important as the infectious agents of the common cold in man. Although there have been reports of chemical agents which inhibit rhinovirus replication, in only a few instances has the mode of antiviral action been demonstrated at a biochemical level^{1,2}.

Although metal ions are well known cofactors in many biological processes, and are inhibitory to some enzymatic reactions^{3,4}, they have received scant attention in virology. We have now examined the abilities of the following metal ions to affect the replication of twelve different picornaviruses in HeLa cells: cadmium, calcium, cobalt, copper, magnesium, manganese, mercury, molybdenum, nickel and zinc. They were supplied as the chloride or acetate, and were tested at 1, 0.1 and 0.01 mM. We used an agar overlay assay described before⁵, but omitted DEAE-dextran. The metals were in-

FIG. 1 Inhibition of cleavages of HRV-1A polypeptides by zinc. A suspension culture of HeLa cells (4×10^6 cells ml^{-1}) was infected with 100 PFU per cell of HRV-1A in the presence of $5 \mu\text{g ml}^{-1}$ of actinomycin D at 34°C . By 4 h after infection host protein synthesis was almost completely inhibited. Identical samples were labelled 4–5 h after infection with $50 \mu\text{Ci ml}^{-1}$ of a ^3H -amino acid mixture in the absence of added zinc (a), in the presence of 0.1 mM ZnCl_2 (b), and in the presence of 0.8 mM ZnCl_2 (c). The whole cells were then solubilised with 1% sodium dodecyl sulphate (SDS), dialysed, and subjected to electrophoresis on $0.6 \times 27 \text{ cm}$ SDS-polyacrylamide gels⁸. Migration was from left to right. The gels were then fractionated and radioactivity was measured with a liquid scintillation spectrometer. The data were analysed using a PDP-10 computer (Digital Equipment Corp.) and the electropherograms were plotted using a CalComp plotter. The gel patterns are photographs of the actual computer output.

incorporated into the agar and added to the HeLa cell monolayers after the virus had been attached to the cells for 1 h. Activity of a particular metal on a virus type was scored as the percentage reduction of the number of virus plaques in the presence of the metal compared with untreated cell

cultures. Toxicity to the cells was not measured quantitatively, but estimated by the loss of stained cells from the plastic Petri dishes after 4 d of incubation in the presence of a given concentration of the metal. If the cells displayed a toxic response, the antiviral activity of the metal at that concentration was not counted.

Only zinc displayed antiviral activity in non-toxic concentrations. Table 1 shows that eight out of nine rhinoviruses were sensitive to 0.1 mM zinc. There was a spectrum of sensitivities, with type 1A being most and type 14 least inhibited. One human rhinovirus, type 5, and two types of poliovirus were insensitive.

To determine the kinetics of zinc inhibition, HeLa cell monolayers infected with HRV-1A were exposed to 0.1 mM zinc at various times during a single replication cycle and the final yield of virus was determined in each case. The results indicated that the addition of zinc at any time during viral replication immediately inhibited further formation of infectious virions.

Two easily assayed processes of picornavirus replication are RNA and protein synthesis. Measurements of the effect of 0.1 mM zinc on total incorporation of ^3H -uridine, or amino acids into HRV-1A macromolecules, indicated that viral RNA and protein synthesis were reduced only by about 10–20%. This slight reduction was not sufficient to explain the marked inhibitions seen in plaque tests (Table 1).

The viral RNA acts as a message in the infected cell to direct the synthesis of the viral polypeptides. Some of the large polypeptides generated during translation are precursor molecules which undergo proteolytic cleavages to produce the smaller viral polypeptides^{6–9}. The most dramatic effect of zinc was to inhibit some of these cleavages of the HRV-1A polypeptides. Figure 1a shows the normal pattern of labelled viral polypeptides formed during 1 h of labelling. Addition of 0.1 mM zinc with the radioactive amino acids prevents post-translational cleavages and causes the accumulation of a set of large precursor polypeptides (Fig. 1b). We found that different cleavages were sensitive to different concentrations of zinc, and that progressively larger polypeptides could be accumulated by increasing the zinc concentration (Fig. 1b and c). Zinc also prevented the cleavage of HRV-2 precursor polypeptides in HeLa cells.

It is significant that the two types of poliovirus which could produce plaques in the presence of 0.1 mM zinc (Table 1) demonstrated normal intracellular polypeptide patterns (not shown) at a zinc concentration which markedly blocked cleavage of HRV-1A polypeptides. In suspension cultures and at higher concentrations of zinc, however, there is marked inhibition of cleavage of certain polio- and EMC viral polypeptides (B.E.B. and B.D.K., in preparation). The cleavage reaction most sensitive to zinc inhibition is the conversion of the capsid precursor, polypeptide 92, (Fig. 1b) to ϵ , γ , and α , the HRV-1A capsid polypeptides^{6–9}. Although other explanations are possible, we suggest that zinc interacts with the HRV-1A capsid proteins (B.D.K. and B.E.B., in

preparation), blocking conversion of the precursor and rapidly preventing maturation of viral RNA and capsid polypeptides.

This report represents a direct demonstration that a chemical which blocks cleavage of viral protein precursors can act (in tissue culture) as an antiviral agent. Recent evidence for polypeptide cleavages during the replication of bacteriophages¹⁰ and many animal viruses⁹, including RNA tumour viruses¹¹, together with the results presented here, suggest that protease inhibitors¹²⁻¹⁴, or zinc may be useful in blocking certain stages of replication of many kinds of viruses.

We thank R. Z. Lockart, jun. for support and critical evaluation during the study. M. Parise, L. Gosser and S. Massado provided technical assistance.

Genetic evidence for SV40 gene function in enhancement of replication of human adenovirus in simian cells

HUMAN adenoviruses undergo a complete cycle of replication in human cells, but cause an abortive infection in simian cells. In the simian cells infected with the human adenovirus, early adenovirus-specific T antigen is induced^{1,2}, viral DNA is replicated to the same level as in productive cycles of replication^{3,4}, and no change in the synthesis of viral mRNA can be detected^{5,6}. However, only limited amounts of viral capsid proteins are made in relatively few cells^{1,2,6-8}. If the simian cells are coinfecting with simian virus 40 (SV40), the nonproductive cycle of replication of human adenoviruses is changed to a productive cycle^{9,10}. This helper effect of infection by SV40 is thought to be under the control of SV40 gene function, but there has been no direct evidence for this. Using temperature-sensitive (*ts*) mutants of SV40, I have now found such evidence.

The isolation and characterisation of (*ts*) mutants of SV40 have been described already^{11,12} and the properties of the mutants are summarised in Table 1. In simian cells,

TABLE 1 Properties of the SV40 temperature-sensitive mutants

† This study.

these mutants replicate well at the permissive temperature of 33° C but not, if at all, at the nonpermissive temperature of 40° C, while wild type parent viruses can replicate equally well at 33–40° C. Genetic analyses have so far revealed three cistrons in SV40 genome and representative mutants of each of three complementation groups (groups I–III) were used in the study described here (Table 1). Human adenovirus type 2 (Ad2) (supplied by Dr K. Fujinaga, Aichi Cancer Centre, Nagoya) was used because it can replicate relatively well at 33°–40° C and because it can be assayed relatively easily in the indicator cells used (fi-8 cells). The stocks of Ad2 were prepared in secondary or tertiary cultures of human embryonic kidney (HEK) cells after the virus had been plaque-cloned twice in HEK cells. The stocks of SV40 and its *ts* mutants were prepared in BSC-1 cells (subline P66) as previously described¹¹. Cultures of singly or doubly infected African green monkey kidney (AGMK) cells were collected for determination of infectivity 42 h (40° C) and 88 h (33° C) after inoculation. The yield of virus in these conditions represents a single cycle of virus development for both SV40 (ref. 11 and 12 and my unpublished observations) and Ad2 (ref. 13 and my unpublished observations).

Table 2 (experiment 1) lists the yield of Ad2, parental SV40, and *ts* mutants of SV40 of complementation groups I and II in the singly or doubly infected cultures of the CV-1 line of AGMK cells at 33° C and 40° C. Clearly the *ts* mutants of SV40 of groups I and II can enhance the replication of Ad2 at 33°–40° C with efficiencies comparable with those in parental SV40-infected cells at 33°–40° C. Essentially similar results were obtained using tertiary cultures of AGMK (Table 2, experiment 3). As it has been suggested that the genes identified in these mutants (cistrons I and II) probably code for SV40 virion proteins¹¹, my results indicate that the function of the SV40 virion proteins specified by these two cistrons is not necessary for the replication of human adenovirus in simian cells. Jerkofsky and Rapp¹⁴ have also shown that other SV40 *ts* mutants, which are probably in the same group as my group I, can help the adenovirus replication in simian cells at the nonpermissive temperature. In confirmation of the previous observations^{7,15}, infection by Ad2 in turn interferes to a great extent with the replication of SV40 in the simian cells (Table 2, experiment 1).

The results of mixed infections with Ad2 and an SV40 *ts* mutant (*ts*640) of complementation group III are shown in Table 2 (experiments 2 and 3). Clearly this mutant fails to enhance the replication of Ad2 at 40° C but not at 33° C both in tertiary cultures of AGMK and in cultures

For the experiment 1, confluent monolayer cultures of CV-1 line of AGMK containing about 2×10^6 cells per 5-cm glass Petri dish were singly or doubly inoculated with 0.5 ml of Ad2, parental SV40 (strain SV40-1), or SV40 *ts* mutants, *ts* 662 (complementation group I) or *ts* 663 (group II). After adsorption at 33°C for 1 h, cultures were washed three times with medium, covered with 4 ml of Dulbecco-modified Eagle's medium containing 5% calf serum and 50 Uml⁻¹ of mycostatin, and incubated at 33°C ± 1°C or 40°C ± 0.5°C in humidified incubators flushed with a CO₂-air mixture. At specified times, cells were collected with medium (two cultures for each point) and stored frozen. After being frozen-thawed more than five times, virus infectivity in the lysates was assayed by plaque formation on cultures of fl-8 line of AGMK transformed by adeno 7-SV40 hybrid virus (E46⁺) (manuscript in preparation) at 37°C (Ad2) and on cultures of BSC-1 line (subline B) of AGMK at 33°C (SV40 and its *ts* mutants). In experiments 2 and 3, confluent 5-cm (experiment 2) or 3-cm (experiment 3) plastic Petri dish cultures containing about 2×10^6 or 7×10^5 cells, respectively, of tertiary AGMK cells or BSC-1 line (subline P66) of AGMK were singly or doubly inoculated with virus. The parental SV40 used was the strain SV68C. After adsorption at 33°C for 1.5 h cultures were treated with anti-SV40 rabbit immune serum for 30 min to remove unadsorbed SV40 and *ts* mutants of SV40 followed by two washings with medium. Cultures were covered with 5 ml (experiment 2) or 2 ml (experiment 3) of Dulbecco-modified Eagle's medium containing 10% foetal bovine serum and 50 Uml⁻¹ of mycostatin. Incubation and collection were the same as in the experiment 1. Virus-infectivity was determined by plaque formation on tertiary cultures of human embryonic kidney cells at 37°C in the presence of anti-SV40 antiserum (Ad2) and on cultures of BSC-1 line (subline B) of AGMK at 33°C (SV40 and *ts* mutants of SV40).

of BSC-1 line (subline P66) of AGMK. This strongly indicates that the SV40 gene controls, either directly or indirectly, the replication of human adenovirus in simian cells. Jerkofsky and Rapp¹⁴ reported that another SV40 early mutant (*ts*A7) can enhance the adenovirus replication at the restrictive temperature. Whether these two early mutants, *ts*A7 and my *ts*640, represent different genes remains to be seen. Since there has been a suggestion that the helper function is correlated with the ability of the cells to be induced to synthesise cellular DNA by infection with SV40¹⁴, it will be interesting, in a future study, to determine whether SV40 and *ts*640 induce cellular DNA synthesis in BSC-1 cells as well as in tertiary AGMK cells. In experiment 2 of Table 2, and occasionally in other experiments, the inhibition of replication of *ts*640 in a single infection of BSC-1 (P66) cells at 40°C was incomplete, in contrast to the complete inhibition in parallel experiments in tertiary AGMK cells (Table 2, experiment 2) or in CV-1 cells (my unpublished observations), suggesting the possibility, among other things, that the cistron III product of SV40 is modified by some cellular factor to carry out its function.

The question is raised: what is the nature of the SV40 gene function identified in mutant *ts*640? A previous study¹² showed that the affected gene was responsible for the synthesis of infectious viral DNA in cells of the BSC-1 line (subline P66) of AGMK and also for the initiation but not for the maintenance of morphological transformation of rat 3Y1 cells. It can be argued that *ts*640 is a double (or triple) mutant but otherwise the gene product affected has three apparently different functions, one in rat cells for the initia-

tion of transformation and the other two in simian cells for the replication of viral DNA and for the facilitation of cell infection by adenovirus. The precise roles of the gene function in each situation and accordingly the relationship between the situations are uncertain. The SV40 mutant defective in these functions described here should prove useful both in understanding adenovirus defectiveness and in defining specific mechanism controlling SV40 DNA replication and cell transformation.

I thank Dr S. Nonaka for primary cultures of African green monkey kidney cells, Drs E. Nakaso and S. Hama for human embryonic kidney cultures, Professor A. Takagi and Dr R. Dulbecco for encouragement, and Mrs Y. Kimura for assistance. This work was supported by grants from the Japanese Ministry of Education.

No crossing over between closely linked tumour virus loci in the heterogametic sex of fowl

RECESSIVE autosomal genes, a^+ , b^+ and c^+ , control the resistance of fowl to Rous sarcoma virus (RSV) of subgroups A, B and C respectively¹⁻⁶. Evidence of a complete or an incomplete linkage between the tumour virus a (tva) and tumour virus c (tvc) loci has been reported⁷ and studies on an F₂ population derived from a cross between C/O (chickens susceptible to subgroup A and subgroup C tumour viruses), and C/AC

The F₁ parents of $a^+a^+c^+c^+$ genotype were derived from a cross between the C/O and C/AC parents. Two test cross (TC) matings were set up. In one, a double dominant heterozygote $a^+a^+c^+c^+$ F₁ male was back-crossed with eight double recessive homozygote, $a^-a^-c^-c^-$ females (TC₁) and in the other eight $a^+a^+c^+c^+$ F₁ females were backcrossed with one $a^-a^-c^-c^-$ male (TC₂). A detailed report on these genotypes and the development of the F₁ and C/AC populations is published elsewhere⁸.

Secondary monolayer cultures of chick embryo fibroblast (CEF) from 11-d-old embryos were individually challenged in pairs with BS-RSV of subgroup A, RSV (RAV49) of subgroup C, and an equal mixture of the two viruses in the same inoculum. Plates were challenged with 0.2 ml of virus suspension diluted to contain 1000 f.f.u. ml⁻¹. Ten days after challenge foci were counted to ascertain resistant and susceptible phenotypes. The detailed procedure of recognition of the four possible subclass phenotypes within dam families and on a population basis, namely C/A (chickens resistant to subgroup A but susceptible to subgroup C); C/C, (chickens resistant to subgroup C but susceptible to subgroup A); C/O, (chickens susceptible to both subgroups) and C/AC, (chickens resistant to both subgroups), is published elsewhere⁸. In designating the phenotypes, the cultures with a focus count of 15 or less were allocated to the resistant class and those above 15 were assigned to the susceptible class.

The distribution of the four subclass phenotypes within dam families and on a population basis for the TC₁, TC₂ and F₂ is shown in Table 1. Based on the observed and expected four subclass phenotype frequency ratios, that is,

TABLE 1 Distribution of four subclass phenotypes within dam families and on a population basis for TC₁, TC₂ and F₂ cultured cells inoculated with BS-RSV, RSV(RAV49) and an equal mixture of the two viruses

(chickens resistant to both subgroups) parents favoured incomplete linkage of these two loci⁸. The linkage value computed from the results of the F₂ population was 0.08 ± 0.03 based on an assumption of equal crossing over in gametes produced by the male and female parents. This report describes the distribution of segregants arising from two reciprocal double back crosses (F₁ ♂ × C/AC ♀ ♀ and F₁ ♀ ♀ × C/AC ♂), which strongly suggests the absence of crossing over in the heterogametic sex (female).

1 C/O: 1 C/A: 1 C/C: 1 C/AC: the χ^2 analysis⁹ for the TC₁ is shown in Table 2. A non-random segregation and re-association of the genes at the tva and tvc loci was indicated by the highly significant χ^2 value, 25.08 ($P < 0.01$). The single degree χ^2 analysis⁹ suggested linkage between the tva and tvc loci, because the segregations of a^+a^+ and c^+c^+ genes were not significant ($P > 0.05$) in contrast to a highly significant χ^2 value, 22.23 ($P < 0.01$), for the joint segregation component (Table 2).

* Significance level; $P > 0.05$.† Significance level; $P < 0.01$.

Nine out of fifty-two were cross over phenotypes (C/A + C/C), and by the maximum likelihood method⁹ the linkage value (p) was estimated to be 0.17 ± 0.05 . On the basis of this p value, the observed phenotype frequencies did not deviate significantly from those of the expected ones ($\chi^2 = 5.52$, $P > 0.05$, Table 2).

The χ^2 analysis for the TC₂, based on observed and expected four subclass phenotypes in a ratio of 1:1:1:1, also gave strong support for linkage between the *tva* and *tvc* loci (Table 3). No cross-over phenotype of either C/A or C/C, out of 40 embryos tested was observed however. It is also possible that very little crossing over had occurred in the TC₂, and that by chance the cross-over products did not appear in this population. This supposition is not testable as p is unknown. Under the assumption of equal p in either TC, that is, $p = 0.17 = TC_1 = TC_2$, the χ^2 value, 12.53 ($P < 0.01$) significantly rejected this postulate (Table 3). Alternatively on the basis of $p = 0.00$, the χ^2 analysis presented in Table 3 favoured the observed 1:1 segregation ($\chi^2 = 3.60$, and $P > 0.05$), which suggests the absence of crossing over in the TC₂.

In the absence of linkage between the *tva* and *tvc* loci, four types of gametes, a^+c^+ , a^+c^- , a^-c^+ and a^-c^- should have been produced by male and female parents at equal frequencies during gametogenesis in the TC₁ and TC₂ respectively. But because of linkage between the two loci the expected frequency distribution of the gametic array was disturbed in proportion to the crossing over between the non-allelic pairs of genes. As a result of differential crossing over in the gametes produced by double heterozygote males of the TC₁ and females of the TC₂, 17% of crossing over was observed in the TC₁ population compared to none in the TC₂. These results and their appropriate χ^2 analysis strongly imply the absence of crossing-over in the heterogametic sex.

This concept was further analysed on the results of the distribution of subclass phenotypes of the F2 population reported earlier⁸. The observed and expected segregation of the four subclass phenotypes of the F2 population is shown in

Table 4. With $p = 0.5$, the χ^2 value was highly significant ($P < 0.01$), indicating a non-random reassociation of genes at the *tva* and *tvc* loci and the linkage test shown in Table 4 confirmed that the *tva* and *tvc* loci are linked ($\chi^2 = 51.81$, $P < 0.01$). In our previous report the results were analysed under the assumption of an equal crossing over in the male and female gametes and the χ^2 analysis supported this concept. Accordingly the p value was estimated to be 0.08 ± 0.03 . The predicted frequency distribution of the four subclass phenotypes, C/O, C/A, C/C and C/AC based on the p value estimated in this study, (0.17 for male and 0.00 for female) is also presented in Table 4. Because the χ^2 value, 0.86 was not significant ($P > 0.05$), the proposed concept of the absence of crossing over in the heterogametic sex of fowl is upheld. The overall p value 0.10 ± 0.03 estimated from the two reciprocal double back crosses, agreed well with that reported previously and by combining the data of the TC₁, TC₂ and F2 populations the best joint estimate of p was 0.09 ± 0.02 . Results obtained from other crosses also support the present findings and will be published elsewhere.

Thus from the results of TC₁, TC₂ and F2 two important conclusions can be drawn: (1) the *tva* and *tvc* loci are linked with a linkage value of 0.17 ± 0.05 , (2) very little or no crossing over occurs between the *tva* and *tvc* loci in the heterogametic sex.

It is an established hypothesis that in many species the heterogametic sex has a strong influence on crossing over during gametogenesis¹⁰. In *Drosophila* the mutant, *c(3)G* in chromosome III has been shown to suppress crossing over in the male¹²; but it is not known whether similar mutants exist in other species.

In fowl, however, sex has little effect on crossing over in all linkage groups except the rose comb-creeper pair¹⁰⁻¹¹. In the latter, crossing over was observed more than twice as frequently in the females as in the males. The results in this study on the other hand, suggest the contrary because very little or no crossing over occurred between the *tva* and *tvc* loci in the female compared with 17% in the male. Because in the fowl the female is the heterogametic sex, the result

TABLE 4 χ^2 linkage test for the detection of linkage between the *tva* and *tvc* loci in the F2 population and segregation analysis of phenotypes based on $p \sigma = 0.17$ and $p \varnothing = 0.00$

in this study therefore supports the present hypothesis that heterogametic sex influences crossing over. In view of the inconsistent sex effect in other linkage groups an explanation of the sex influence on crossing over in the *tva-tvc* linkage pair is difficult without further studies. It may be that the F1 females of the strain of fowl under study are carrying structural chromosomal changes, such as inversion and translocation, which could influence crossing over indirectly¹². A careful cytological study might show such changes.

I thank Dr L. N. Payne for reading the manuscript and G. Baldock for expert technical assistance.

Scrapie in sheep selectively bred for high susceptibility

THE enigma of scrapie disease of sheep is still unresolved, in spite of intensive efforts—especially over the past 12 yr—to elucidate its pathogenesis and to define the transmissible agent. Various hypotheses on the nature of scrapie remain unproved¹⁻¹⁰.

It has long been recognised that heredity is an important factor in the transmission of naturally-occurring scrapie. In 1961 a selective breeding programme with Herdwick sheep was started at this Institute, with the objective of developing from the same foundation stock, two flocks, one highly

Fig. 1 Case A: a scrapie-affected ram. Note dullness, rubbed areas and hind-limb weakness.

Fig. 2 Case A: a histological section of the medulla oblongata. There is extensive spongiform degeneration of the 10th nucleus. Stained with haematoxylin and eosin (X25).

susceptible and the other highly resistant to experimental scrapie. This objective has now been achieved¹¹. Briefly, in two successive years 40 rams and 699 ewes were mated in forty separate flocks to produce two crops of lambs. One crop of lambs and their parents were then challenged with scrapie by inoculation. A proportion of the inoculated animals developed scrapie during the following 2 yr. The non-inoculated crop of offspring could then be defined in terms of the susceptibility to scrapie of their parents and their sibs. Animals of which the parents and sibs developed scrapie were the foundation stock for the present flock that is highly susceptible to experimental scrapie; likewise, the foundation stock of the highly resistant flock had parents and sibs that did not develop scrapie.

The breeding part of this programme has been carried out exclusively in five buildings well separated from each other on a restricted and clearly defined experimental area of the 2,000 acre estate that is part of this Institute. Neither natural nor experimental scrapie had ever been present in this area before the occurrence of the two cases of the disease described here. Sheep to be inoculated with scrapie have always been removed to one of two other clearly defined areas on the estate, each approximately 1 mile away. Different shepherds have looked after the breeding flocks and infected flock, respectively. The isolation of the breeding flocks has been strictly maintained.

Both the cases of scrapie that are the subject of this communication have occurred in the flock that has been bred for high susceptibility to experimental scrapie. The first (case A) was in July 1972 in a ram 40 months old. Clinical signs of scrapie were typical, and included rubbing over the rump, hind-limb incoordination and weakness, and a dull facial expression (Fig. 1). The second (case B) was in November 1973 in a ewe 43 months old. Again, the clinical signs were typical and closely similar to those of case A. Both animals were observed for a few days and were then killed for *post mortem* examination. In both cases histological examination of the brain showed in the medulla oblongata the characteristic bilaterally symmetrical spongiform encephalopathy of scrapie, with vacuolation of the neurones; spongiform change was particularly marked in the region of the 10th nucleus (Fig. 2). Neurones showing foamy vacuolation (Fig. 3) were present in both cases. This type of vacuolation is typical of natural scrapie, and is rare in the experimentally produced disease¹². Also, in both cases vacuolated neurones were more obvious and more numerous than is usual in the experimental disease^{12,13}.

Because the histopathology of these two cases was that of naturally-occurring scrapie, a histological re-examination was made of the 99 cases of scrapie that have occurred in

Herdwick sheep inoculated at this Institute over the past 6 yr with a standard dose of a pool of homogenised scrapie sheep brain. A single section of the medulla oblongata close to the calamus scriptorius¹⁴ from each of these 99 brains was compared with single sections of the same area from cases A and B. Particular attention was paid to vacuolated neurones, foamy vacuolation of neurones and spongiform vacuolation of the 10th nucleus. The results are shown in Table 1. These results indicated strongly that the scrapie of cases A and B differed from the experimental scrapie produced by the standard inoculum. Because scrapie can still be defined only in clinicopathological terms, no other test was available to differentiate between these two expressions of the disease. It may be noted, however, that both cases occurred at ages (40 and 43 months) close to the mean of 39 months in the highly characteristic age incidence pattern recorded by Parry² for 1,008 cases of naturally-occurring scrapie.

Scrapie cases A and B both occurred in the flock bred for high susceptibility to experimental scrapie. Although they had four common ancestors, they were not very closely related to each other. The coefficient of inbreeding¹⁵ of case A was 0.063, and of case B was 0.008.

The mechanism of the spread of scrapie disease has been extensively studied.¹⁶ It is generally accepted that natural scrapie is usually perpetuated in a hereditary manner, and the very rare exceptions in which there has apparently been lateral spread may have been related to ingestion of foodstuff contaminated by foetal membranes voided by a scrapie-affected ewe at lambing time¹⁷. The experimental disease does not spread by contact, unless—as may happen with rodents—there has been ingestion of scrapie tissue. It is extremely unlikely, therefore, that scrapie cases A and B could have occurred by either direct or indirect contact with natural or experimental scrapie. They were separated in time by 16 months, and the physical organisation of the experimental programme makes it impossible that they were accidentally inoculated with scrapie; even had this been so, the histopathology would have been that of the experimental disease.

I conclude that these two cases of scrapie arose spontaneously by genetic selection in a breeding programme designed to increase susceptibility to experimental scrapie. This conclusion supports the proposition put forward by Parry² that in the naturally-occurring disease the scrapie agent can be formed within susceptible sheep, and it agrees with the long-established fact that scrapie is frequently associated with attempts to improve the conformation and performance of sheep by inbreeding¹⁸.

A genetic basis for the development of scrapie in sheep is consistent with observed facts, but it leaves unresolved the problem of the nature of the transmissible agent. A majority of investigators have assumed that the agent is self-replicating because its titre in body tissues rises during sub-clinical and clinical development of the disease. Self-replication implies involvement of nucleic acid. Nucleic acid, however, has not been identified, and there is impressive experimental evidence from ultraviolet irradiation studies

FIG. 3 Case B: a histological section of the medulla oblongata showing foamy vacuolation of a neurone. Stained with haematoxylin and eosin (X105).

that it may not be present in the agent¹⁹⁻²². Pattison and Jones⁵ pointed out that if the scrapie agent were present in normal tissues in an inhibited form and if it were gradually released as scrapie developed, this unmasking would provide an alternative explanation to self-replication. It seems possible that a mechanism such as this could be genetically controlled, and that resultant disorganisation of metabolism could cause degeneration of the central nervous system.

I thank Mr N. V. Elcock for care of the animals, Mrs R. M. Pocock for calculating the inbreeding coefficients, Mr P. F. Dennis and Mr B. A. Turfrey for the histological preparations, and Mr M. H. Jebbitt for the photographs.

Anti-muscarinic properties of neuroleptics and drug-induced Parkinsonism

ONE unifying hypothesis of the behavioural effects produced by neuroleptic drugs is that they act by blocking dopamine receptors in the central nervous system¹⁻³. Neuroleptic drugs produce increases in dopamine turnover⁴, increase accumulation of its metabolites⁵, antagonise amphetamine induced behaviour in man and animals⁶ and block the stimulating effects of dopamine on cyclic AMP production in homogenates of rat brain striatum or mesolimbic nuclei⁷⁻⁹.

One complication in the use of these drugs is that they often produce severe extrapyramidal side effects including a syndrome similar to idiopathic Parkinsonism^{10,11}. This syndrome has been explained as a blockade of dopamine receptors by the drugs resulting in a functional lack of dopamine in the basal ganglia. The extrapyramidal side effects may be treated by centrally acting anticholinergic agents¹² which restore the balance between the antagonistic dopaminergic and cholinergic influences in the basal ganglia¹¹ without interfering with the antipsychotic actions of the neuroleptics.

It has been shown⁸ that a series of neuroleptics differed over a 50-fold range in their ability to inhibit the striatal dopamine-sensitive adenylyl cyclase (Table 1). The more potent antidopaminergic drugs, however, are used clinically in much lower doses than the less potent drugs and on this basis one might therefore expect all neuroleptics to produce about the same incidence of extrapyramidal signs. That this is not the case has become increasingly apparent. In particular the phenothiazine, thioridazine, and the recently described dibenzodiazepine, clozapine, have been shown to produce very few extrapyramidal motor side effects¹³⁻¹⁵. Clozapine has been shown to be an anticholinergic agent using the guinea pig ileum and it has been suggested that the paucity of extrapyramidal side effects seen with this drug was a result of this property¹⁶⁻¹⁸. In the present experiments we have used a specific radioactive affinity label for muscarinic receptors to determine if any relationship exists between drug induced Parkinsonian signs and anti-muscarinic activity in neuroleptic drugs.

Male Wistar rats were decapitated and their brains removed. The cerebral cortex was homogenised in 10 volumes of ice cold 0.32 M sucrose. Protein concentration was determined by the method of Lowry *et al.*¹⁹ and the homogenate was diluted in Krebs-Henseleit solution (equilibrated with 5% CO₂ in oxygen) to give 0.27 mg protein ml⁻¹. 3 ml aliquots of homogenate were preincubated for 15 min with the drug being tested and then the aziridinium ion from N-2'-chloroethyl-N-[2'', 3'', ³H]-propyl-2-aminoethylbenzi-

FIG. 1 Inhibition of atropine-sensitive uptake of ³H-PrBCM by neuroleptic agents and other drugs. Experiments were performed in quadruplicate and standard errors were < 10%. The lines are theoretical mass action curves derived using the dissociation equilibrium constants given in Table 1. Atropine-sensitive uptake was approximately 60% of a total uptake of 700 pmol ³H-PrBCM per g protein. ●, Atropine; Δ, benztropine; ■, ethopropazine; +, thioridazine; ▽, clozapine; ▲, chlorpromazine; ○, pimo- zide; ▼, flupenthixol; □, trifluoperazine; ×, spiroperidol.

late (³H-PrBCM: 1.8 Ci mmol⁻¹) added to give a final concentration of 2 × 10⁻⁹ M. The aziridinium ion was prepared as described by Burgen *et al.*²⁰. Incubation was continued for 8 min and was stopped by the addition of 20 ml Krebs-Henseleit solution containing 10 mM sodium thio- sulphate. Samples were filtered under suction through Whatman GF/C glass fibre filters, washed with 20 ml of Krebs-Henseleit solution and the tritium remaining on the filters determined by liquid scintillation counting.

The concentration of ³H-PrBCM used produced 88% receptor occupation in an uninhibited reaction. Percentage inhibition of the rate constant of alkylation was determined by the method of Burgen *et al.*²¹. Dissociation equilibrium constants were derived from the slope of the plot (fractional inhibition of rate constant)⁻¹ against (concentration of reversible inhibitor)⁻¹.

The effect of different drug concentrations on the atropine-sensitive binding of ³H-PrBCM in cortical homogenates is shown in Fig. 1. Dissociation equilibrium constants for the various drugs are listed in Table 1. The most potent drug used was the classical antimuscarinic agent, atropine, which was included for comparison. It is clear that the neuroleptics differ over a wide range (approximately four orders of magnitude) in their antimuscarinic potencies. The results obtained here support the hypothesis that the antimuscarinic activity of these drugs is related to the frequency of extra- pyramidal side effects. For example, in considering drugs of the phenothiazine class one finds a spectrum of effects. These drugs range from trifluoperazine, a potent dopamine receptor blocker with little antimuscarinic activity, that causes a high frequency of extrapyramidal effects, through chlorpromazine and thioridazine to ethopropazine, a drug with no neuroleptic effects, which has in fact been used as an anti-Parkinsonian agent¹¹. The antimuscarinic effect of benztropine, a classical anticholinergic, anti-Parkinsonian agent¹¹ is shown for comparison. The incidence of extra- pyramidal effects found with the other drugs is also in- versely related to their antimuscarinic activity. Spiroperidol, a butyrophenone and flupenthixol, a thioxanthene, have weak antimuscarinic effects and produce frequent side ef- fects¹³. Clozapine produces few side effects and is a con- siderably more potent antimuscarinic agent.

Several other observations concerning the behavioural and metabolic effects of neuroleptics may also be interpreted in the light of these results. Thus, clozapine causes a smaller

TABLE 1 Dissociation equilibrium constants of various drugs for cortical muscarinic receptors

Drug	Dissociation equilibrium constant (M)	IC ₅₀ for striatal* dopamine-sensi- tive adenylyl cyclase (M)
Atropine	5.2 ± 0.3 × 10 ⁻¹⁰	—
Benztropine	1.3 ± 0.1 × 10 ⁻⁹	> 10 ⁻⁴
Ethopropazine	1.0 ± 0.1 × 10 ⁻⁸	—
Thioridazine	2.5 ± 0.1 × 10 ⁻⁸	3.0 × 10 ⁻⁶
Clozapine	5.5 ± 1.0 × 10 ⁻⁸	4.5 × 10 ⁻⁶
Chlorpromazine	3.5 ± 0.2 × 10 ⁻⁷	1.0 × 10 ⁻⁶
Pimozide	1.6 ± 0.1 × 10 ⁻⁷	4.5 × 10 ⁻⁶
Trifluoperazine	4.0 ± 0.4 × 10 ⁻⁶	4.0 × 10 ⁻⁷
Flupenthixol	2.2 ± 0.8 × 10 ⁻⁶	7.0 × 10 ⁻⁸
Spiroperidol	1.2 ± 0.1 × 10 ⁻⁵	2.0 × 10 ⁻⁶

The dissociation equilibrium constants are determined as in the text. The effect of some of these compounds on striatal dopamine-sensitive adenylyl cyclase is shown for comparison.

* Data from Miller and Iversen, 1974⁸.

increase in homovanillic acid accumulation in basal ganglia than in the limbic system of rabbits¹⁷ and thioridazine produces little increase in homovanillic acid accumulation in monkey basal ganglia¹. In addition, it has recently been suggested that the different effects of thioridazine and chlorpromazine in antagonising amphetamine-induced turning in rats, argue against dopamine receptor blockade being involved in neuroleptic activity²². These results, however, may be explained by the more potent antimuscarinic activity of thioridazine.

In conclusion, the results presented here support the hypothesis that neuroleptic drugs with potent antimuscarinic activity produce few Parkinsonian side effects. Combination of the method used here with an *in vitro* measure of dopamine receptor blockade, such as the dopamine-sensitive adenylyl cyclase, should ensure improved and rapid selection of potentially useful neuroleptic agents.

In the course of this study we learned of a similar series of experiments performed by Snyder, Greenberg and Yamamura²³. The results of their work seem to agree with those reported here.

We thank May and Baker Ltd, Janssen Pharmaceutica Lundbeck Ltd and Wander Ltd for supplying drugs.

Inhibition of normal clotting and Fletcher factor activity by rabbit anti-kallikrein antiserum

NORMAL human plasma clots rapidly on contact with a foreign surface such as glass, through a sequence of reactions designated the intrinsic pathway of thrombin formation. Two nearly identical mechanisms, designated a waterfall¹ and cascade² respectively, were proposed to explain this process. Although these hypotheses have since been modified³, ideas about the clotting factors involved and the essential order of their participation have not changed. Many of the reactions have been clarified through the use of plasma from patients with congenital deficiencies and partially purified preparations of clotting factors.

Hathaway *et al.*⁴ described a family in whom impaired blood clotting seemed to be due to the deficiency of a hitherto unrecognised clotting factor. The defect, designated Fletcher factor deficiency or Fletcher trait, after the affected kindred, has been recognised in at least three further patients⁵. Wuepper⁶ reported that Fletcher trait plasma is functionally and antigenically deficient in a plasma prekallikrein, and that the addition of purified preparations of prekallikrein corrected the clotting defect of Fletcher trait plasma. This observation, confirmed in this and other laboratories^{7,8}, suggests that a plasma prekallikrein or its activated form, kallikrein, participates in normal blood clotting. To examine this possibility further, we have prepared antiserum in rabbits against purified human plasma kallikrein and examined its effect on the clotting of normal human plasma. We report here that this anti-kallikrein antibody impedes the intrinsic pathway of thrombin formation by depleting normal plasma of Fletcher factor activity.

Partially purified human plasma kallikrein was prepared from human oxalated plasma by tricalcium phosphate adsorption, Celite 512 adsorption and elution, and successive column chromatography on SP-Sephadex C-50, QAE-Sephadex A-50 and Sephadex G-150 (Pharmacia, New Market, New Jersey)⁹. The preparation released 26.4 μ M methyl alcohol (MeOH) $\text{ml}^{-1} \text{h}^{-1}$ (specific activity: 775 μ M MeOH mg^{-1} protein h^{-1}) from *p*-toluenesulphonyl-L-arginine methyl ester¹⁰ and approximately 250 ng of bradykinin per ml in the rat uterus assay¹¹. The kinin generating activity was inhibited by soybean trypsin inhibitor (0.5 mg ml^{-1}) and Trasylol (500 U ml^{-1}), but not by lima bean trypsin inhibitor (0.5 mg ml^{-1}). It contained traces of activated PTA activity (less than 0.005 U ml^{-1}), but no measurable amount of other known clotting factors or plasmin.

TABLE 1 Effect of anti-kallikrein antibody on screening tests of blood coagulation

Test	Clotting time	
	Normal rabbit γ G + normal plasma	Anti-kallikrein antibody + normal plasma
	(s)	(s)
Thrombin time*	31.4	32.8
One-stage prothrombin time	16.8	16.8
Russell's viper venom time	11.9	12.6
Kaolin-activated partial thromboplastin time†	67.0	298.4

A sample of 0.4 ml normal human pooled plasma was incubated with equal amounts of either normal rabbit γ G (21 mg protein per ml) or anti-kallikrein antibody (33 mg protein per ml) in a 10 \times 75 mm polystyrene tube at 37° C for 60 min. The mixture was then tested. The techniques used in these tests have been summarised before¹².

* 2.5 NIH U/ml crude bovine thrombin (Parke, Davis, Detroit).

† 0.1 ml test sample was incubated with 0.1 ml kaolin-Gliddex-P in a 10 \times 75 mm glass tube at 37° C 1 min before adding 0.1 ml 0.025 M CaCl₂.

Rabbit antiserum to human plasma kallikrein was obtained by injecting a mixture of equal parts of partially purified kallikrein, containing approximately 50 μ g protein, and alumina C γ -gel (A grade, Calbiochem), into the footpads of New Zealand albino female rabbits. Four weeks later

TABLE 2 Effect of anti-kallikrein antibody on some clotting factors in the intrinsic pathway

Clotting factor	Dilution of anti-kallikrein or normal rabbit γ G	Clotting time			
		Normal rabbit γ G + normal plasma		Anti-kallikrein antibody + normal plasma	
		(s)	(%)	(s)	(%)
Hageman factor	Undiluted	66.2	100	68.6	86
PTA	Undiluted	121.5	100	116.6	105
Christmas factor	Undiluted	120.9	100	121.5	100
AHF	Undiluted	111.5	100	112.8	100
Fletcher factor	Undiluted	103.6	100	378.2	<1
Fletcher factor	1/2	—	—	378.8	<1
Fletcher factor	1/4	—	—	335.7	<1
Fletcher factor	1/8	—	—	224.6	2.5

A sample of 0.05 ml normal human pooled plasma was incubated with equal amounts of either normal rabbit γ G (21 mg protein per ml) or various dilutions of anti-kallikrein antibody (33 mg protein per ml) in 10 \times 75 mm polystyrene tubes at 37° C for 60 min. Then, 1.9 ml ice-cold barbitol-saline buffer (0.025 M barbitol-sodium barbitol, 0.125 M sodium chloride, pH 7.5) was added to each tube and 0.1 ml aliquots were assayed for each clotting factor listed above. The assays of Hageman factor, PTA, Christmas factor and AHF were performed as described before¹⁶ on substrates of plasma from patients with congenital clotting deficiencies. Fletcher factor was assayed by incubating a 0.1 ml test sample with 0.1 ml kaolin-Gliddex-P and Fletcher trait plasma in 10 \times 75 mm glass tubes at 37° C for 1 min. 0.1 ml 0.025 M CaCl₂ was then added to the tubes and the clotting time was measured at 37° C. The results were expressed as the clotting time and as the percentage of activity relative to that in the mixture with normal rabbit γ G.

the rabbits received a further injection of this kallikrein without adjuvant. Antiserum was collected 1 week thereafter. When subjected to immunodiffusion in 0.9% Agarose, the unabsorbed antiserum gave three precipitin lines with normal, Hageman trait or plasma thromboplastin antecedent (PTA)-deficient plasma, but only two lines with Fletcher trait plasma. After absorption with Fletcher trait plasma, the antiserum was adsorbed with tricalcium phosphate, subjected to 60° C for 60 min to inactivate clotting factors, and the γ -globulin fraction was separated by treatment with *n*-octanoic acid and ammonium sulphate¹². As a control, normal rabbit γ -globulin was prepared in the same way. The γ -globulin prepared from absorbed anti-kallikrein serum (anti-kallikrein antibody) formed a single precipitin line of identity against normal, Hageman trait or PTA-deficient plasma, and purified kallikrein or prekallikrein, whereas it formed no recognisable line against Fletcher trait plasma. The absorbed anti-kallikrein antibody retained the ability of unabsorbed antiserum to neutralise the kinin-generating activity of purified plasma kallikrein.

Normal human pooled citrated plasma, prepared from twenty-five normal adult males, was incubated with equal amounts of either normal rabbit γ -globulin or anti-kallikrein antibody at 37° C for 60 min. The mixtures were then tested in screening tests of blood coagulation. The thrombin time, prothrombin time and Russell's viper venom time were the same in both mixtures (Table 1). In contrast, the kaolin-activated partial thromboplastin time (kaolin PTT) was prolonged considerably in a mixture containing anti-kallikrein antibody (298.4 s) compared with that of a mixture containing normal rabbit γ -globulin (67.0 s).

These experiments suggested that the anti-kallikrein anti-

body interfered with an early phase of the intrinsic pathway. Four clotting factors have been recognised as participants of this stage: Hageman factor (factor XII), PTA (factor XI), Christmas factor (factor IX) and antihemophilic factor (AHF, factor VIII). The functional activity of each of these clotting factors, assayed after incubation of normal plasma with anti-kallikrein antibody at 37° C for 60 min, was unaltered, as though the prolonged kaolin PTT was not due to the neutralisation of these clotting factors (Table 2). The Fletcher factor activity of normal plasma, assayed on the substrate of Fletcher trait plasma, however, was reduced sharply by incubation with as little as a four-fold dilution of anti-kallikrein antibody (less than 1% activity compared with a control). These experiments demonstrated that the incubation of normal plasma with anti-kallikrein antibody resulted in the impaired clotting through the intrinsic pathway by depleting its Fletcher factor activity.

The use of anti-kallikrein antibody in this study further supports the view that a plasma kallikrein may be required for the *in vitro* intrinsic pathway of blood coagulation. The exact site at which kallikrein participates in the intrinsic pathway is not yet settled, but evidence has been obtained that kallikrein may be required for the action of the activated Hageman factor¹³. Recently, Gjønnæss presented data suggesting that under certain conditions the extrinsic pathway of blood clotting may also be activated through an action of a plasma kallikrein on factor VII¹⁴. These studies serve once again to emphasize the intimate relationships between different systems of host-defense mechanisms, here the clotting and the kallikrein-kinin system.

We thank Ms Janet Shlaes for technical help and Dr Charles C. Abildgaard and Paul J. Hattersley for the Fletcher trait plasma. This study was supported in part by grants from the National Heart and Lung Institute, National Institutes of Health, and the American Heart Association, of which O.D.R. is a career investigator and H.S. is a research fellow.

Lectin purification using formalinised erythrocytes as a general affinity adsorbant

MANY carbohydrate-binding proteins, called lectins, purified from plant extracts¹, are proving useful for the study of protein-carbohydrate interactions, cell-surface-initiated differentiation of cells and the topography of cell surface constituents^{1,2}. A general method for purification of lectins would markedly augment this work. Affinity chromatography has been successful for purification of some lectins³ although others require conventional chemical fractionation. Purification may be simplified by the availability of commercial carbohydrate polymer adsorbants: for example Sephadex G-50³ for concanavalin A and Sepharose 4B for the carbohydrate-binding protein from *Dictyostelium discoideum*⁴.

Affinity chromatography can be difficult, however, if adsorbants must be manufactured. Purification of lectins would be easier if a general class of natural insoluble affinity adsorbants were available. Since lectins are generally identified by the ability to agglutinate erythrocytes of an appropriate type, we have tried formalinised erythrocytes as the affinity adsorbant. They have the advantage of being stable, not lysing in hypotonic or hypertonic media or when exposed to high concentrations of lectins. We found that formalinised erythrocytes bind lectins efficiently and release them on addition of appropriate sugars. Our method makes possible preparation of highly purified lectins with a minimum of effort and should prove applicable to all proteins which bind to carbohydrates on cell surfaces.

Crude plant seed extracts (Table 1) were assayed for the ability to agglutinate several types of formalinised erythrocytes⁵, and the type which gave the highest agglutination titre was used for purification. Assays were performed in microtitre V plates (Cooke Engineering) using serial two-fold dilutions of the extracts. Each well contained 25 μ l of lectin solution in 0.15 M NaCl (buffered to pH 6.4 for assays of concanavalin A) and 25 μ l of a 2.5% (v/v) suspension of formalinised erythrocytes in 0.15 M NaCl. Patterns were read 45 min after starting the reaction. The affinity of the erythrocyte adsorbant for lectin was determined by adding various amounts of erythrocytes to crude extract, shaking for 10 min and assaying the adsorbed supernatant for residual lectin activity after centrifugation at 10,000g for 10 min. For all lectins a ratio of erythrocytes to crude extract was chosen such that at least 95% of agglutination activity was adsorbed.

For purification the predetermined amounts of extract and formalinised erythrocytes were combined, and 0.15 M NaCl

was added to bring the final volume to a 30% (v/v) cell suspension, which was incubated at room temperature for 30 min with gentle shaking. The cells were then washed four times with 10 cell volumes of saline with centrifugation at 3,000g for 5 min. The lectin was eluted by shaking the washed cells (30% v/v) in 0.15 M NaCl containing 0.3 M sugar. After 30 min the supernatant was collected by centrifugation at 5,000g for 5 min, recentrifuged at 10,000g for 20 min and then exhaustively dialysed against 0.15 M NaCl to remove the sugar. The formalinised erythrocytes could be washed and used for another purification.

By this procedure, we obtained highly purified lectins in high yield from four plant sources (Table 1). Crude extracts containing concanavalin A and wheat germ agglutinin (WGA), were purified partially before adsorption to erythrocytes, whereas *Ulex* and lima bean lectins were purified directly from crude extracts. The binding capacity of the formalinised erythrocytes varied but was always sufficiently high for efficient purification. Under the conditions used binding was in the range of 0.4–1.7 mg lectin per packed ml of erythrocyte adsorbant and recoveries ranged from 50 to 100%. In all cases substantial quantities of pure lectin could be obtained with small amounts of adsorbant, so that conventional centrifugation facilities are adequate for preparative procedures several orders of magnitude larger than reported here.

The purity of the lectins was determined by polyacrylamide gel electrophoresis in a sodium dodecyl sulphate (SDS) system (Fig. 1). With concanavalin A, WGA and lima bean agglutinin a single protein band was observed after staining. With *Ulex* we found approximately equal amounts of two closely migrating proteins. All molecular weights agreed with previous determinations—WGA, 23,000⁶; lima bean, 30,000⁷; concanavalin A, 25,000⁸. With *Ulex*, the two closely migrating bands have molecular weights of 43,000 and 45,000. The subunit molecular weights of this lectin have not been reported previously, but the molecular weight of the intact molecule is approximately 160,000⁹. Thus, the *Ulex* lectin may be a tetramer. Commercially available WGA and concanavalin A (Miles) were identical by SDS gel analysis with our purified products. The agglutination activity per mg protein of these commercial lectins was equal to or slightly less than those prepared in our laboratory.

These findings suggest that formalinised erythrocytes can be used as a general affinity adsorbant for the purification of lectins from many sources. The simplicity of the method and the high yields and purity of the product recommend it for general use.

TABLE 1 Purification of four lectins by adsorption to formalinised erythrocytes

Source	mg Crude protein added to suspension	FE type	FE (packed ml)	Eluant	mg Recovered	% Lectin recovered*
Jack bean meal	9	Chicken	3	α -Methyl-D-mannopyranoside	1.7	57
Wheat germ lipase	84	Human Type A ₁	3	N-Acetyl-D-glucosamine	2.9	60
<i>Ulex europaeus</i> seeds	64	Human Type O	3	L-Fucose	1.8	50
Lima beans (<i>Carolina sieva</i>)	300	Human Type A ₁	5	N-Acetyl-D-galactosamine	2.0	100

FE, formalinised erythrocytes. Crude extracts from jack bean meal (Sigma) and wheat germ lipase (Miles) were partially purified according to published procedures¹¹, whereas crude extracts of *Ulex europaeus* seeds (F. W. Schumacher Co., Sandwich, Massachusetts), and lima beans (W. Atlee Burpee Co., Clinton, Iowa) were used directly. The jack bean meal was extracted in 0.15 M NaCl. The extract was concentrated with (NH₄)₂SO₄ and dialysed against 0.15 M NaCl. The product was adsorbed to formalinised erythrocytes. The wheat germ lipase was suspended in water, heated for 10 min at 58°C, chilled to 4°C, centrifuged at 10,000g for 15 min and the supernatant filtered, concentrated by ultrafiltration and made up to final concentration of 0.25 M NaCl, 0.05 M sodium phosphate, pH 7.0 before formalinised erythrocytes were added for adsorption. *Ulex europaeus* seeds and lima beans (100 g of each) were ground in a coffee grinder and extracted in 1.5 l 0.15 M NaCl for 15 h at 4°C with gentle shaking. The resulting suspension was filtered through cheesecloth, centrifuged at 10,000g for 30 min, concentrated by ultrafiltration and adsorbed with formalinised erythrocytes.

* % of lectin activity present in the initial extract which was recovered in the final product.

FIG. 1 Polyacrylamide gel electrophoresis of purified lectins. Lectins (100 to 300 μ g) were dissolved in 0.1% SDS, 0.01 M β -mercaptoethanol, applied to 10 cm polyacrylamide gels (2.5% stacking gel, 7.5% running gel) and electrophoresed in 0.1% SDS, 25 mM Tris, 192 mM glycine, pH 8.4. The gels were stained with Coomassie blue¹² and molecular weights estimated by comparison with protein standards¹³. Cytochrome c (Cyt) was added to all samples. a, *Ulex* agglutinin; b, lima bean agglutinin; c, concanavalin A; d, wheat germ agglutinin.

In a search of the literature for a method which might be similar to ours we found that Avrameas and Guilbert¹⁰ used glutaraldehyde-fixed erythrocyte stromata as affinity adsorbents for lectins. Since neither the binding capacity of this adsorbent for lectins nor the electrophoretic purity of the products are described, it is difficult to compare their method with that described here.

Autoradiography of intravenously injected ¹⁴C-nicotine indicates long-term retention in the respiratory tract.

INVESTIGATIONS using autoradiography¹ to monitor the distribution in mice of ¹⁴C-labelled nicotine administered intravenously showed a consistently high concentration in the entire respiratory tract. A number of mice, some of them pregnant, were each given a single intravenous dose and then were autoradiographed at postinjection times varying between 5 min and 30 d. The injected dose was 0.4 μ Ci per g body weight (corresponding to 1.79 μ g nicotine per g body weight) for the non-pregnant mice, and 0.25 μ Ci per g body

FIG. 1 Details of autoradiograms of mice, a, 24 h and, b, 30 d after intravenous injection of ¹⁴C-nicotine. Note the marked accumulation and retention in the bronchi (white areas).

weight (corresponding to 1.12 μg nicotine per g body weight) for the pregnant mice. The nicotine used was labelled in the methyl group (The Radiochemical Centre, Amersham, England, specific activity 73 μCi per mg^{-1}). Autoradiograms of whole body sagittal sections of the mice were made as described earlier¹. The times of exposure varied from 2 to 4 weeks.

At 5 min there were many sites of localisation in addition to the respiratory tract, such as the central nervous system (CNS), ganglia, and the adrenal glands which have previously been reported by our coworkers^{2,3}. After 1 h and later, the respiratory tract was increasingly dominant in the distribution picture as the radioactivity disappeared from the other areas. The main site of accumulation seemed to be the respiratory mucosal lining: the nasal mucosa, larynx, trachea and bronchi (Fig. 1a). The same pattern persisted after 30 d, although the concentration in the bronchi had now decreased it was still significant (Fig. 1b).

Most other tissues were rather rapidly cleared of the radioactive substance. After 30 d, however, there was still a low level present in the skeletal muscles and in the myocardium. Radioactive material was also observable in the urinary bladder. Although less persistent, a high uptake and retention could also be seen in the oesophageal mucosa.

In the pigmented animals a strong and persistent accumulation occurred in the tissues containing melanin. This has earlier been observed for many polycyclic drugs and seems (providing the dose exceeds a certain critical level) to cause damage of the tissues involved, for example, the skin, eye, inner ear and substantia nigra of the brain^{4,5}.

Long term accumulation in the respiratory tract, however, has not been previously observed in our autoradiographic studies of various types of chemicals. In full term fetuses, a selective accumulation could be seen in the respiratory tract (larynx, trachea and bronchi) and in the melanin bearing tissues.

Further investigations are needed to establish the chemical structure of the labelled compound which accumulates in the respiratory tract. To judge from the rapidity with which the uptake proceeds, it seems likely that the nicotine is trapped as such, but may later be metabolised. The mechanism of accumulation also needs further investigation. Affinity for some endogenous substance in the respiratory mucosal cells is one possibility.

If the observed accumulatory mechanism is also present in humans, smoking may lead to a considerable retention of some nicotine derivative in the respiratory mucosa. Oddly enough, an accumulation should also be expected if nicotine is administered by other routes than by inhalation (such as the use of snuff, chewing tobacco and nicotine tablets). It might, therefore, be worthwhile to look into the possible role of this accumulatory mechanism with respect to the pathogenesis of respiratory cancer and of bronchitis.

This investigation was supported by grants from the Swedish Tobacco Co., and from The Swedish Board of Technical Development.

Effect of thiocyanate on nitrosation of amines

CARCINOGENIC nitrosamines are formed by chemical reaction between nitrous acid and secondary and some tertiary amines in the stomachs of rodents¹⁻³. Nitrosamines could be formed similarly in the human stomach and so present a carcinogenic hazard to man. The nitrosation reaction is catalysed by some anions⁴ particularly thiocyanate^{5,6}. Thiocyanate is secreted in saliva which in non-smokers normally contains about 50 mg l^{-1} (approximately 1 mM) but in smokers contains three to four times this concentration⁷. In the absence of catalyst the nitrosation of N-methylaniline and some other secondary amines is maximal at pH 3, but in the presence of thiocyanate the reaction proceeds much more rapidly in acid conditions, such as in gastric juice, between pH 1 and 2 (Fig. 1). At pH 1.5, 1.0 mM thiocyanate increases the rate of reaction about 550 times. Under these acid conditions below pH 2 the nitrosation reaction rate is proportional to the concentrations of (1), nitrite; (2), thiocyanate; and (3), amine⁸. At pH 3.5 and greater thiocyanate has less catalytic action and the predominant reaction is proportional to the square of the nitrite concentration, but is slow.

FIG. 1 Initial rate of reaction of N-methylaniline (0.1 mM) and sodium nitrite (0.1 mM) with various concentrations of sodium thiocyanate against pH at 25° C. a, thiocyanate absent; b, 0.025 mM thiocyanate; c, 0.1 mM thiocyanate; d, 0.25 mM thiocyanate; e, 1.0 mM thiocyanate.

The volume of saliva secreted by man is about 1.5 l d⁻¹ and that of gastric juice between 2 and 3 l d⁻¹. If the daily intake of water in food and drink were 3 l d⁻¹ then saliva would be diluted some five-fold in the stomach. The thiocyanate concentration in the stomach could therefore be about 0.2 mM in non-smokers and 0.6 mM in smokers; these concentrations of thiocyanate would increase the nitrosation reaction 100 and 300 times at pH 2. Saliva also contains up to 200 mg l⁻¹ nitrate^{9,10} which is probably derived from food, water and tobacco smoke. Some of the nitrate is reduced to nitrite in the mouth. The smoke from a cigarette contains oxides of nitrogen which might produce 0.5 mg of nitrite in the body so that 20 cigarettes could yield 10 mg nitrite. This amount of nitrite could also be present in 200 g of ham or Frankfurter sausages.

Cigarette smoke contains cyanide compounds which are converted to thiocyanate in the body by the action of rhodanese (thiosulphate-sulphur transferase). The smoke from a cigarette contain up to 0.5 mg cyanides which could yield double this amount of thiocyanate. The daily output of saliva of smokers, however, contains some 200 mg more thiocyanate than that of non-smokers. Thiocyanate is secreted both by the kidney and salivary glands and the volumes of urine and saliva are about the same. Smoking generally increases the flow of saliva¹¹.

Non-smokers excrete three times more thiocyanate in urine than in saliva, that which is secreted in saliva being reabsorbed from the alimentary tract. In smokers the urinary and salivary thiocyanate excretions are about equal. Thus smoking seems to change the route of thiocyanate excretion either by inhibition of kidney secretion or stimulation of salivary secretion. Although cigarette smoke inhibits the activity of rhodanese of guinea pig tissues it increases the thiocyanate concentration of the salivary glands, lung, kidney and brain¹². This is because rhodanese activities are high and smoke contains cyanide compounds.

Nitrosamines are formed in cigarette smoke by the reaction of oxides of nitrogen with secondary and tertiary amines. The most abundant nitrosamine in cigarette smoke seems to be nitrosornicotine¹³ which is carcinogenic¹⁴ and formed from nicotine. The formation of nitrosornicotine would be greater in the more acid smoke of British cigarettes than in the less acid smoke of other cigarettes, cigars or pipes. The synthesis of nitrosamines in the stomach is probably greater in smokers than non-smokers because of the hydrocyanic acid and oxides of nitrogen present in tobacco smoke. Reduction in the concentration of oxides of nitrogen in tobacco smoke should reduce the amount of nitrosamines formed by the smoke itself and in the stomach.

Thymidylate concentration in megaloblastic anaemia

MEGALOBlastic anaemia is thought to be caused by a disturbance of DNA synthesis in the bone marrow. The most common causes are deficiencies of folate or vitamin B₁₂ which are thought to interfere directly or indirectly with supply of thymidine triphosphate (dTTP, thymidylate) one of the four immediate precursors of DNA^{1,2} (Fig. 1). We have previously shown that acute folate deficiency caused by the antifolate drug, methotrexate, does indeed cause a fall in the intracellular concentration of dTTP³. The present paper reports studies of the cellular concentration of dTTP and of the other three deoxyribonucleotide precursors of DNA, deoxyadenosine triphosphate (dATP), deoxyguanosine triphosphate (dGTP) and deoxycytidine triphosphate (dCTP) in the bone marrow cells and phytohaemagglutinin (PHA)-stimulated lymphocytes from patients with untreated megaloblastic anaemia due to vitamin B₁₂ or folate deficiency. Surprisingly, no reduction in dTTP concentration was found in either cell.

Bone marrow was obtained from 20 patients with untreated megaloblastic anaemia (16 Addisonian pernicious anaemia, 4 nutritional folate deficiency). Their haemoglobin levels ranged from 3.1 to 9.8 g per 100 ml and all had florid megaloblastic marrow changes and adequate iron stores. Peripheral lymphocytes were obtained from 15 of these patients. Normal control subjects consisted of 70 healthy adult members of the medical and technical staff of the Hammersmith Hospital. Bone marrow samples were obtained from 13 of these normal subjects and from 14 adult patients with untreated acute myeloid leukaemia in relapse (30–90% blast cells in the marrow).

The deoxyribonucleotide concentrations in bone marrow are shown in Table 1. The levels of all four, dATP, dGTP,

Bone marrow cells were collected into 5 ml ice-cold Hanks' balanced salt solution containing 500 units sodium heparin. After centrifugation, mature red cells were haemolysed in distilled water for 30 s before restoration of isotonicity with 0.6 M KCl. The cells were washed once in ice-cold phosphate-buffered saline. Extraction of the deoxyribonucleotides was performed by adding 1 ml 60% methanol, cooled to -20°C , to the cell pellet⁴. The tubes were then stood overnight at 4°C before removal of the methanol by evaporation. The assay of the deoxyribonucleotides has been described^{5,6}. For estimation of dATP and dTTP, poly(dA-dT) was used as primer while for dGTP and dCTP, DNA was used as primer. Radiochemicals were purchased from Radiochemical Centre, Amersham, poly(dA-dT) and DNA polymerase (*Micrococcus luteus*) from Miles Laboratories and calf thymus DNA from Sigma Laboratories.

Results are expressed as pmol per 10^6 cells.

dTTP, and dCTP, were greater in megaloblastic than normal marrow cells. It is known, however, that proliferating cells, in general, show greater deoxyribonucleotide concentrations than resting cells⁷. Since megaloblastic marrows contain a greater proportion of primitive cells than normal, the levels of the DNA precursors are also compared with those in the bone marrows of patients with untreated myeloblastic leukaemia which also contain a high proportion of primitive (albeit abnormal) cells. There was a wide variation in individual results, but there was no significant difference between the mean dTTP concentration in the marrow cells of patients with untreated megaloblastic anaemia and acute myeloblastic leukaemia. The ratio of dTTP concentration to that of dATP, dGTP or dCTP, was also similar in these two diseases.

The mean deoxyribonucleotide concentrations in PHA-stimulated lymphocytes from patients with megaloblastic anaemia were not significantly different from normal at either 48 h or 72 h of culture (Table 2). In particular, the dTTP concentrations were similar in megaloblastic and normal lymphocytes. In neither bone marrow nor peripheral lymphocytes were the deoxyribonucleotide concentrations different between the folate-deficient and vitamin B₁₂-deficient megaloblastic cells (not shown).

These results show that the free concentrations of the immediate precursors of DNA, the four deoxyribonucleoside triphosphates, are normal in the PHA-transformed lymphocytes of patients with untreated megaloblastic anaemia. The concentrations of these four precursors are increased in megaloblastic bone marrow compared with normal bone marrow, but only in keeping with the increased proportion of primitive cells in megaloblastic marrow compared with normal. No selective reduction of thymidine triphosphate (dTTP) concentration could be demonstrated in either cell system as might have been expected both on the basis of previous observations of a block in thymidylate synthesis in bone marrow and in PHA-stimulated lymphocytes of patients with untreated megaloblastic anaemia^{1,2} and on the basis of more recent observations of a dramatic decrease in cell dTTP concentration produced by methotrexate *in vitro*³.

Various theories may be proposed to explain the rather surprising finding of a normal cell thymidylate concentration

in megaloblastic anaemia. It seems most likely to us that compensation has occurred in the cells of patients with chronic folate or vitamin B₁₂ deficiency to maintain normal cell dTTP concentrations despite defective synthesis of thymidylate from deoxyuridylate (Fig. 1). This compensation could take the form of increased salvage of preformed thymidine from degradation of DNA in the bone marrow and in other tissues. The activity of the enzyme, thymidine kinase, which is necessary for the salvage of preformed thymidine is indeed increased in the bone marrow cells and PHA-transformed lymphocytes in untreated megaloblastic anaemia^{9,10}. Moreover, intramedullary haemolysis would lead to excessive release of preformed thymidine in the marrow in megaloblastic anaemia. Slow DNA synthesis, known to be a feature of megaloblasts¹¹, could also contribute to maintenance of the dTTP concentration by reducing utilisation of dTTP.

Some other explanations for the normal dTTP findings are possible. It could be that the present finding of normal dTTP concentrations in megaloblastic anaemia is artefactual as a result of replenishment of the dTTP concentration *in vitro* in our cultures but this is unlikely. Though the medium, TC 199, used for culture of lymphocytes does contain thymine, 10^{-6} M, culture in a specially prepared thymine-free TC 199 made no difference to the measured dTTP concentration in PHA-stimulated megaloblastic lymphocytes from three patients (unpublished observations). Further, the bone marrow dTTP estimations were made on marrow samples cooled in Hanks' solution (free of thymine or thymidine) and extracted immediately after aspiration. Another potential source of artefact is that a compound which accumulates in megaloblastic cells other than dTTP might be measured as dTTP by the technique used here. We have no evidence to support or refute this possibility, though in view of our finding of a consistent decrease in measured dTTP concentration with methotrexate *in vitro*³, we feel it is unlikely. A further possibility is that an overall normal cellular dTTP concentration in megaloblastic anaemia may mask an intracellular redistribution of this compound with a reduction in nuclear dTTP masked by a increase in the extranuclear concentration of this compound. Hydroxyurea, which inhibits DNA synthesis mainly by antagonism of ribonucleotide reductase, has also been suggested to damage the nuclear mem-

TABLE 2 Deoxyribonucleoside triphosphate concentrations in human PHA-stimulated lymphocytes

Lymphocyte cultures were set up in autologous serum and TC 199 as described⁸ except Triosil-Ficoll was used instead of iron filings to remove neutrophils. Cultures of 3×10^6 cells were made in 1 ml autologous serum and 2 ml TC 199 (Biyroughs-Wellcome) and 0.1 ml PHA. After 48 or 72 h, the cells were washed twice in ice-cold phosphate-buffered saline.

Results are expressed as pmol per 10^6 cells

brane, and loss of deoxyribonucleotides from the nucleus may play a part in its action¹². Further studies of the sub-cellular localisation of dTTP in megaloblasts are, therefore, necessary. Finally, there has been discussion whether the mono or diphosphate rather than the triphosphate derivatives of the deoxyribonucleosides are the immediate DNA precursors. We have not measured the cell concentration of thymidine mono or diphosphate in megaloblastic anaemia but recent evidence does firmly support the deoxyribonucleoside triphosphates as the crucial precursors¹³.

In a previous study⁸ we found that acute folate deprivation caused by methotrexate *in vitro* in PHA-stimulated lymphocytes caused an increase in dATP concentration as well as a decrease in dTTP. The present results show that in chronic megaloblastic anaemia there is no increase in dATP but that the dATP concentration parallels that of the other deoxyribonucleotide triphosphates. Compensations must have occurred to balance the deoxyribonucleotide pools at a slower rate of DNA synthesis in the chronic state.

Whatever the explanation for the normal deoxyribonucleotide concentrations in untreated megaloblastic anaemia, our results provide further information on the disturbance of DNA synthesis in this disorder and complement previous observations that the base composition of the DNA itself is normal in the bone marrow in untreated megaloblastic anaemia¹⁴. They are consistent with the view that slowed DNA synthesis in some way gives rise to the characteristic morphology and intramedullary cell death of megaloblastic anaemia.

We thank the physicians of Hammersmith Hospital and Dr I. Chanarin, Northwick Park Hospital, Dr G. Marsh, North Middlesex Hospital, Dr E. Offerman, Whittington Hospital, Dr J. Parker-Williams, Central Middlesex Hospital and Dr P. D. Roberts, West Middlesex Hospital for providing peripheral blood and bone marrow samples. A.V.H. thanks the Medical Research Council and Leukaemia Research Fund for financial support. A.L. is in receipt of a Fellowship from the Medical Research Council of Canada, and M.H.N.T. is a Medical Research Council Clinical Research Fellow.

Catecholamine transport through a lipid barrier

NORADRENALINE and adrenaline are stored in relatively high concentration together with nucleotides (mainly adenosine-5'-triphosphate (ATP)), bivalent cations (for example Ca^{2+} and Mg^{2+}) and water-soluble proteins, in special intracellular organelles such as chromaffin granules of adrenal medulla¹. In the uptake of catecholamines by these organelles a specific mechanism is probably involved at the level of the granular membrane². Furthermore, formation of low molecular weight complexes between catecholamines and ATP^{3,4} and mixed amine-nucleotide aggregates of apparent high molecular weight⁵⁻⁸ has been demonstrated. The present experiments deal with the role of these interactions for the uptake and storage of the amines. Evidence will be presented that an 'uphill' transport of neurotransmitters occurs if ATP is present on one side of an artificial lipid barrier and that this effect is connected with a reduction in the osmotic pressure of the biogenic monoamines by ATP.

Permeation studies were carried out at 37° C with commercially available equipment (resorption model of Stricker, SM 16750, Sartorius-Membranfilter GmbH, Göttingen), consisting of a diffusion cell with two compartments, A and B, of equal size (100 ml) separated by an artificial lipid barrier, and a peristaltic pump for the circulation of the aqueous solutions along the lipid barrier. The latter, which had an effective size of 80 cm² and a thickness of about 100 µm, was prepared by soaking a membrane filter (type RS, Sartorius, Göttingen) at 30° C with a mixture of 97.7% lauryl alcohol and 2.3% diethyl succinate. (–)-Noradrenaline (0.0095 mol l⁻¹) (purum, Fluka, Buchs) or 0.0055 mol l⁻¹ (–)-adrenaline (crystalline, Merck, Darmstadt) or 0.0083 mol l⁻¹ β-phenethylamine (Sigma, St Louis) were dissolved together with 0.024 mol l⁻¹ CaCl_2 in K-Na phosphate buffer of pH 5.8 (molarity: 0.067). ATP (0.10 mol l⁻¹) was added to the solution in compartment B, but not to A. The pH of the

FIG. 1 Transport of noradrenaline through a lipid membrane from compartment A to compartment B at 37° C. Both compartments contain 0.0059 mol l⁻¹ noradrenaline at the beginning of the experiment. Compartment B also contains 0.10 mol l⁻¹ ATP. The pH in both compartments is adjusted to 5.8 and remains constant during the experiment. 100%, Noradrenaline concentration at the beginning of the experiment; a, compartment A; b, compartment B; c, compartments A and B in the absence of ATP in compartment B. Results are the averages of four experiments.

Fig. 2 Effect of added catecholamines on osmolality of an aqueous solution of 0.19 mol l⁻¹ ATP, containing CaCl₂ in a molar ratio to ATP of 0.24 to 1, at 37° C. a, Catecholamine = noradrenaline; b, catecholamine = adrenaline. Results are average of three experiments.

solutions was readjusted to 5.8 with 2 N NaOH. Auto-oxidation of noradrenaline was prevented by adding 0.01% ascorbic acid (Hoffmann-La Roche, Basel) and by bubbling nitrogen through the solutions during the course of the experiments. The concentrations of noradrenaline⁹ and of ATP¹⁰ were checked by fluorescence spectroscopy, those of adrenaline and β -phenethylamine by ultraviolet spectroscopy. Analysis by fluorescence spectroscopy showed that the artificial lipid barrier was impermeable to ATP, corresponding in this respect to membranes of amine storage organelles¹¹.

Osmolalities were determined by isothermal distillation¹² at 37° C using aqueous NaCl as reference solutions. The osmolalities of all solutions were estimated by measurement of freezing point depression with a semi-micro osmometer (Knaur, Berlin). Controls of the osmotic pressure of the solutions of inorganic ions by isothermal distillation at 37° C showed that their osmolalities were practically independent of temperature. The osmotic pressure due to the inorganic ions was subtracted, so that the results presented in the graph corresponded to ATP (0.19 mol l⁻¹) and its mixtures with the catecholamines only. The pH of the solutions containing noradrenaline (0.76 mol l⁻¹) in a molar ratio to ATP of 4 to 1 was 5.8, that of the solutions of lower molar ratios or with ATP only correspondingly lower (0.6). Control experiments with adjustment of the pH of the ATP solution to 5.8 (using 2 N NaOH) in the absence of noradrenaline gave evidence that the pH effect on osmolality was negligible.

Figure 1 shows the 'uphill' transport of noradrenaline at 37° C. The amine content was the same in both compartments at the beginning of the experiment (0.0059 mol l⁻¹), but compartment B also contained 0.10 mol l⁻¹ ATP. During the experiment, the noradrenaline concentration in compartment A decreased markedly (curve a), and correspondingly an increase occurred in compartment B (curve b). Adrenaline behaved similarly to noradrenaline. No change in catecholamine concentration was to be seen in the absence of ATP from compartment B (curve c). Transport of noradrenaline into the ATP-containing compartment also occurred at higher

initial concentrations of the amine on both sides of the lipid barrier.

Figure 2 demonstrates the effect of the addition of noradrenaline and adrenaline on the osmolality of 0.19 molar aqueous solution of ATP at 37° C. The solutions also contained CaCl₂ in a molar ratio to ATP of 0.24 to 1. The results indicate that mixtures of ATP and noradrenaline and of ATP with adrenaline have substantially lower osmotic pressures than ATP alone. The fraction of catecholamines present in the dissociated state in these mixtures was about 10–20% (based on calculations of apparent average molecular weights obtained by isothermal distillation, sedimentation equilibrium and velocity experiments). In contrast, noradrenaline hydrochloride was dissociated to about 70–80% in the same range of concentrations (determined by isothermal distillation at 37° C). Minimum osmotic pressure existed at a molar ratio of 2:1, catecholamines to ATP, the osmotic pressure of ATP being reduced by a factor of 4 and 2.5 by the addition of noradrenaline and adrenaline respectively. On increasing the molar ratio to greater than 2:1, the osmotic pressure rose again, but even at a ratio 4:1 it was still lower than that of ATP alone.

The accumulation of catecholamines in the ATP-containing compartment B was probably due to intermolecular bonding between the amines and the nucleotide, which is confirmed by our osmolality measurements. Because of the interaction of catecholamines and ATP, the concentration of free catecholamines available for diffusion is likely to decrease in the ATP-containing compartment B, giving rise to a concentration gradient between compartments A and B of the free (diffusible) amine. The catecholamines would then penetrate by diffusion from compartment A into compartment B, where most of them are bound to ATP. The overall displacement of catecholamines from A into B probably stops when the concentration of the free catecholamines in the two compartments is the same. This view is supported by the finding that β -phenethylamine, which does not accumulate in the ATP-containing compartment of the diffusion chamber, did not display marked aggregation with ATP in the sedimentation equilibrium and velocity experiments (our unpublished observations).

The present results with an artificial lipid membrane show that in the presence of ATP and bivalent cations, catecholamines can be accumulated against a concentration gradient without a specific, energy-dependent transport mechanism being present. This finding confirms the previous hypothesis by which intragranular formation of aggregates between amines, nucleotides, bivalent cations and possibly proteins is an essential mechanism for the uptake and storage of biogenic amines by adrenal chromaffin granules and probably by other storage organelles, blood platelets for example¹³. A tentative structure for the intragranular organisation of catecholamines and ATP has recently been proposed¹⁴.

In conclusion, our experiments provide direct evidence that transport and accumulation of catecholamines can occur as a consequence of their aggregation with ATP. This aggregation may considerably increase the efficiency of the granular membrane pump in storing biogenic amines.

The contribution of activation processes to the length-tension relation of cardiac muscle

It is generally agreed that the form of the length-tension relation of a fully activated skeletal muscle is determined by the overlap of actin and myosin filaments within the sarcomere. Figure 1 shows the length-tension curve for tetanised frog skeletal muscle¹, which is thought to be fully activated at lengths above 75% L_{max} (ref. 2). This is the form of the curve that would be expected from any muscle of similar sarcomere structure to frog muscle, provided that it has a constant degree of activation (either complete or partial) at muscle lengths above 75% L_{max} . The sarcomere structure of cardiac muscle is similar to that of frog muscle³, yet the shape of its length-tension curve is strikingly different (Fig. 1). In skeletal muscle deviation from the 'ideal' curve shown in Fig. 1 has been attributed to variation in the degree of activation when the muscle is stimulated at different lengths. We have investigated this possibility in cardiac muscle by studying the effect on the length-tension

Fig. 1 The length-tension relationships for skeletal (Sk) and cardiac (C) muscle. The ordinate is the developed tension as a percentage of the maximum developed tension (P_{max}) and the abscissa is the length as a percentage of the length (L_{max}) at which developed tension is maximum. There is evidence that the sarcomere spacings at L_{max} are similar in frog skeletal and cat papillary muscle³. The dashed line on the skeletal muscle curve is the region over which activation may be incomplete².

Fig. 2 Experimental records of twitch responses of a cat papillary muscle (L_{max} 3.3 mm, diameter 0.6 mm) to electrical stimulation at 20 min⁻¹. *a*, Experimental sequence used to obtain the length-tension curves shown in Fig. 3. The length of the muscle is first decreased and then increased again in five equal steps of 0.165 mm (5% L_{max}). Tension is measured in newtons. *b*, This shows an alternative sequence in which the muscle was held at each length for five beats; the difference between the first beat after a change of length and subsequent beats is attributed to the presence of a series viscoelastic element in the preparation. Note that tension production takes several minutes to recover to its previous steady level after the muscle has been returned to its original length. *c*, High speed (oscilloscope) records of the twitch responses during the descending part of the tracing shown in *a*.

relation of varying the degree of activation produced by electrical stimulation: we have done this by altering the concentration of calcium in the bathing medium and by using paired pulse stimulation⁴.

The experimental procedure was as follows. An isolated papillary muscle from the right ventricle of a kitten was stimulated electrically at 30° C to give isometric twitch contractions every 3 s (see ref. 5 for further details about technique). The length-tension curve was determined as quickly as possible by changing the length of the muscle between successive beats (Fig. 2*a*), starting near L_{max} and working down to a length at which no increase in tension was detectable on stimulation and then returning in similar steps almost to L_{max} . This procedure avoided the complications introduced by the slow changes in tension development that occur when the muscle is allowed to contract for a longer period at short lengths (compare Fig. 2*b* and *a*). The value of L_{max} was then estimated by stretching the muscle in smaller steps until the developed tension (peak tension minus resting tension) started to fall. The entire procedure was performed when the calcium concentration in the bathing solution was 2.0 mM, 0.5 mM, 8.0 mM and then repeated at 2.0 mM.

The resting tension and peak tension were measured at each length and the values obtained on the ascending and descending limbs of the cycle were averaged to minimise the influence of a viscous element or other factors⁵ which might make the first beat at lengths below L_{max} different from subsequent ones (see Fig. 2*b*). The results have been plotted in two ways, as in Fig. 3*a* and *b*, which show the data obtained from a representative muscle. In Fig. 3*a* the peak tension and resting tension are given in N mm⁻² as a function of the actual muscle (mm), and the estimated value of L_{max} is marked on each curve. The length-tension relation for the resting muscle is unaffected by changes in the calcium concentration, but the curve for peak tension is affected in several ways: there is a very slight shift of L_{max} to longer muscle lengths when the calcium concen-

tration is raised, but the main effect is a large potentiation of tension development, which is proportionally greatest at short muscle lengths. This is clearly seen in Fig. 3a, but it becomes much more obvious when the data are replotted so that the maximum tension developed at each calcium level is normalised to 100% and muscle lengths are expressed as a percentage of L_{max} (Fig. 3b). If the normalised curves are not superimposable at lengths other than L_{max} , then the intervention must have altered the degree of activation relatively more at these lengths than at L_{max} : the implication of this would be that activation processes in the muscle are length-dependent. Thus the conclusion from the results in Fig. 3b is that the form of the length-tension relation of cardiac muscle depends at least in part on a variation in the degree of activation with length. The 2 mM- Ca^{2+} data shown in Fig. 3 (and comparable data from three similar experiments) suggest that the form of the length-tension relation changes slightly with time, but any such effect is too small to affect our conclusion.

Since the 8.0 mM curve is shifted towards that expected from the sliding filament theory, one wonders if by increasing the activation further a curve which approximated more closely to the sliding filament theory could be obtained. To this end we have increased the degree of activation by paired pulsing which in some circumstances may produce tensions close to the maximum of which the muscle is capable at that length⁴. This altered the shape of the length-tension relation, but only to approximately the same extent as 8.0 mM calcium.

One possible objection to our results is that peak tension is not a satisfactory index of contractility if the time to peak tension is altered by the intervention being investigated (see Fig. 2c)⁶. However, the length-tension relation for $(dP/dt)_{max}$, an index of contractility that is unaffected by changes in time to peak tension, varied with the calcium level in just the same way as the length-tension relation for developed tension (Fig. 3b). The argument that tension changes in parallel elastic structures might have interfered in some way with our measurements can also be dismissed because the difference we have noted in the form of the length-tension relation is present at lengths where there is no resting tension (Fig. 3a). We have also considered the possibility that the change seen in the normalised curve could be due to the presence of an internal load that increases in size as the muscle length decreases (such a load must exist because the relaxed length of a muscle is greater than the shortest length to which it can contract). Although

this is a possible explanation, quantitative estimates of the size of the load required to produce the observed shift in the normalised curves are not consistent when two of the curves in Fig. 3b are used to predict the shift in the third one; furthermore, the size of the load required to produce the observed effects decreases rather than increases at shorter muscle lengths.

Thus, it appears from Fig. 1 and the results shown in Fig. 3 that in cardiac muscle, as in frog skeletal muscle under some conditions (such as tetanic contractions at short muscle lengths², twitch contractions at room temperature⁷), the form of the length-tension relation is not determined simply by the properties of the sliding filament system. In both types of muscle length-dependent activation processes appear to have an important influence on the form of the curve, at least at lengths below L_{max} . As cardiac muscle is probably confined to working below L_{max} under physiological conditions because of its large resting elasticity, this is a matter of considerable practical importance, but at this stage the nature of the length-dependence of activation processes can only be a matter of speculation. The fact that peak tension is reached sooner at short muscle lengths (Fig. 2c) suggests that deactivation associated with shortening is occurring⁸, and observation of the muscles operating at the foot of their length-tension curve confirms that they are visibly slack at rest and must therefore shorten appreciably before exerting tension. Incomplete activation due to failure of the inward spread of excitation to centrally-placed myofibrils⁹ seems less likely in cardiac muscle than in skeletal muscle because of the much smaller diameter of the cardiac muscle cell.

It seems that in heart muscle in contrast to skeletal muscle the rise in intracellular Ca^{2+} concentration produced by each action potential is insufficient to give full activation of the contractile system. The degree of activation is thought to be affected by the rate of stimulation and extracellular Ca^{2+} concentration¹⁰, the duration of the action potential¹¹, and the effect of various drugs¹²; and the observations reported here provide evidence that muscle length is another factor of importance in determining the completeness of the excitation-contraction coupling process.

Pattern reconstitution in abdominal segment of *Leucophaea maderae* (Blattaria)

DURING the past few years the cuticular patterns of insect segments has been looked at with increasing interest. Following transplantations of pieces of epidermis¹⁻⁵ all these patterns become remodelled in a characteristic way. Analysis of the patterns led to the idea of a segmentally reiterated gradient. According to this concept any line of a segment with its specific structure is characterised and possibly determined by a specific level of the gradient.

Many of the experiments dealing with the problem of the mutual correlations between the segmental gradient and pattern formation have been performed in the bug *Rhodnius*^{2,6}. In this species the cuticular pattern of the tergites consists of medio-laterally oriented surface ripples. When square pieces of the integument are cut out and rotated through 90° the orientation of cuticular structures in the transplant gradually approaches the normal orientation during the following moults.

There are two main ways this reconstitution of the pattern could occur. (1) It is assumed that the gradient has many of the properties of a concentration-diffusion gradient. A cell differentiates and secretes its specific cuticle according to the level at which it happens to lie. A change of the level of the gradient in the surroundings of the cell is followed by a change of the differentiation properties of the cell; the cell is 'reset' to the new level. Thus the reconstitution of the pattern after a 90° rotation is due to the levelling of discontinuities of the gradient by processes similar to diffusion and the subsequent redifferentiation of the cells. The cells of the transplant remain in their rotated position but change their polarity and pattern. Computer simulations based on these propositions showed agreement with the observed cuticular patterns.⁶ (2) It is assumed that the gradient features and the differentiation properties of the cells are more stable and cannot be changed by diffusion-like processes. The approximation of the pattern towards normality after the 90° rotation could be brought about by a bodily rerotation of the whole transplant. In this case the cells of the transplant would change their position relative to the host tissues but preserve their original differentiation properties. Similar rerotations of grafts had been observed in the eyes of amphibia⁷ and in the legs of cockroaches⁸.

In *Rhodnius* there are no proper epidermal and cuticular markers which could allow a clear decision between the two alternatives. So it seemed desirable to make similar experiments in species better suited for this purpose. This and the following two papers describe rotation experiments performed on the tergites of two hemipteran species and of a cockroach⁵.

Larvae of *Leucophaea maderae* were used for the experiments. The cuticular pattern of the larval tergites consists of two areas: the anterior half of the tergite has a more or less smooth cuticle with only a few tiny bristles; the posterior half has a cuticle with many tubercles of different size in a regular but individually variable distribution. The two fields are separated by a prominent transversal ridge. Square pieces of integument containing the ridge and parts of both regions were cut out and reimplanted after a rotation through 90°. The angle between the ridge of the transplant and a reference line in the host segment was measured on the mounted cuticles of the successive larval instars up to the imago.

As shown in Fig 1a-f the angle between the ridge of the transplant and the reference line diminishes gradually during the following moults. The bristles and tubercles in the central area of the transplant stay in a more or less constant position relative to the ridge (Fig 1g-k). Thus the whole pattern rotates back towards the original position.

The pattern of bristles and tubercles on the tergites of

Leucophaea is highly variable; no two segments have an identical pattern. If it is assumed that after the rotation of the transplant the cells are reset to new gradient levels and according to their new levels generate a new pattern one would expect that the distribution of bristles and tubercles in the newly formed pattern would be different from that in the original. The observation of an identical pattern rotating back towards the original position is a strong indication for a rerotation of the transplant tissues as a whole. The entire pattern changes are not to be explained purely

FIG. 1 a-f, Development of an anticlockwise rotated piece of skin during the following moults up to the imago. The cuticle of one instar (between d and e) had been lost. The angle between the ridge of the transplant and a reference line (between insertions of left and right dorso-ventral muscles) diminishes from 96° to 55°. At the right (g-k) the corresponding region of the transplant is shown at a higher magnification. Part of the bristles and tubercles are outlined by circles to demonstrate that the relative positions of ridge, bristles and tubercles of most parts of the transplant remain more or less unchanged; the pattern as a whole rotates back. Magnifications: a, $\times 101$; b, $\times 92$; c, $\times 83$; d, $\times 76$; e, $\times 51$; f, $\times 51$; g-k, $\times 303$.

by rotation however, since this could not explain how the ridge of the transplant joins up with that of the host. The generation of intermediate gradient values by intercalary regeneration is one possible explanation.

Though it is only the pattern on the cuticle whose rotation can be observed in *Leucophaea* there is no doubt that the epidermis of the transplant, too, rotates back since the cuticle is only a secretion product of the epidermis. More direct evidence for the movement of the epidermis is presented in the following contributions^{9,10}. So pattern reconstitution in the tergites of *Leucophaea* is, at least mainly, brought about by a rerotation of the transplant tissues; it is not necessary to assume a resetting of the cells. In this respect the epidermis of the tergites is like the legs in which a resetting to new levels seems to be possible only in proliferating tissues⁵.

The mechanics of the rerotation has not been studied in detail up to now. Muscle contraction as a means for movement can be excluded since the transplant region is completely free of muscles. Most likely the rotation is achieved by an active movement of the border cells, while the more central parts are carried along with them passively as can be judged from the unchanged pattern of large central parts (Fig. 1g-k; see also ref. 10). Pushing the transplant by intercalary regeneration should also be taken into account.

Cell movement during pattern regulation in *Oncopeltus*

THE cuticle of adult *Rhodnius* (Hemiptera) is marked by mediolaterally oriented surface ripples. From transplantation and rotation experiments on the epidermis Locke¹ demonstrated a segmentally reiterated gradient. We² have proposed a model of the gradient which is considered as a concentration of some diffusible substance, the direction of steepest slope of concentration specifying cellular polarity and thereby the orientation of the ripples. We suggested that the cells might contribute to the stability of the gradient and attempt to maintain their original or 'set' level when transposed.

Rotation of a larval square of epidermis through 90° results in an S-shaped pattern of ripples in the adult cuticle. When such an adult is made to moult again to produce a second cuticle the S-shaped pattern flattens, so that the ripples are now aligned nearer to the mediolateral axis. This change of pattern was associated with the presence of cell divisions in the artificial moult cycle; when the moult cycle was truncated and cell divisions omitted, the first and second

FIG. 1 Camera lucida drawings showing the result of transplanting a piece of orange epidermis containing a transparent clone (shaded) on to a white fourth-stage host. The graft was rotated through 90° clockwise. a, The situation immediately on grafting (clone rotated c. 93°); b, the young fifth-stage (angle of clone now c. 85°); c, the adult (angle of clone now about 65°).

cuticular patterns were almost identical. We therefore suggested that the cells' set level was re-established at some stage in the cell division cycle allowing further diffusion and consequent changed polarity. An alternative cause of pattern change could be bodily rotation of the entire graft in the opposite direction to that of the original experiment⁹. This paper and the two accompanying contributions^{3,4} show that in fact there is bodily rotation of the graft.

Pieces of epidermis were exchanged between wild type (orange pigmented cells) and a mutant, *wb* (white pigmented cells) of *Oncopeltus fasciatus*⁵. The adult hairs and cuticular tubercles were used as polarity indicators, both normally

FIG. 2 A strip of orange epidermis (long axis mediolateral) was rotated through 90° clockwise and transplanted on to a white fourth-stage larva. In the adult the strip of orange cells is still clearly visible and still retains the same orientation as it had on grafting (long axis antero-posterior). As in the host, the hairs in the graft point posteriorly.

pointing posteriorly. Following X-irradiation as eggs⁶, fourth-stage larvae were screened for long thin clones which were a different colour than orange and had their long axes parallel to the mediolateral axis of the body. Square pieces of epidermis containing such clones were excised, rotated through 90° and implanted on a white host in the centre of the segment. The graft border and shape and orientation of the clone were drawn by camera lucida in the two succeeding instars (Fig. 1). In some cases the clone was damaged by the operation but in all five cases where the clone survived as a coloured strip, there was clear evidence for the rotation of the clone and therefore for bodily rotation of the graft; in no case did the central hairs become reorientated while the clone remained in the original orientation. In one case the clone itself became S shaped suggesting more cell movement at the edges of the graft.

My unpublished experiments on *Dysdercus fasciatus*, and those of Nübler-Jung⁴ on *D. intermedius* suggest that the rotation of grafts is restricted to a relatively short period (about 20 h⁴) when the epidermis separates from the cuticle; that is, after cell divisions have ceased.

In a second series of experiments (suggested to me by Dr H. Bohn) thin strips of epidermis, with their long axes oriented mediolaterally were taken from orange *Oncopeltus* larvae, rotated through 90° and transplanted on to white larvae. When the graft survived as a strip, it remained oriented close to the anteroposterior axis, but the orientation of the hairs, and the small epidermal tubercles turned so that they pointed posteriorly (Fig. 2).

These two classes of experiments show that the situation is complex; the first shows that cell movement is an important component of pattern regulation, and the second that regulative changes of polarity can occur without bodily rotation of the entire graft. It is still possible that regulation of polarity is achieved by smaller parts of the graft rotating independently. Rotation back of grafts has been demonstrated in other systems (the amphibian ear⁷ and eye⁸, and the insect leg⁹), while polarity changes that are not dependent on rotation are found after juxtapositions of regions from different levels in the axis of both the abdominal segments² and the legs of insects⁹. These changes are associated with cell division.

Cell migration during pattern reconstitution in the insect segment (*Dysdercus intermedius* Dist., Heteroptera)

If in the insect segment a piece of epidermis is rotated through 90° the changed pattern tends to return to normal after several moults.¹ This observation can be explained by a rotation of the whole transplant (ref. 2 and H. Bohn, personal communication) or by a resetting of the trans-

FIG. 1 Development of a transplant rotated anticlockwise through 90° during the third larval instar. *a*, Aspect early in the fourth instar; *b*, late fourth to early fifth instar; *c*, shortly before metamorphosis. Posterior segment border at the bottom. Scale, 100 μm.

posed cells.³ Until now it was not possible to decide between these two mechanisms since pattern reconstitution in the leg or body segment was studied only by the observation of cuticular structures such as bristles and ripples⁴. These structures reflect the physiological status of the epidermal cells only during the short periods of epicuticle formation but not during the intervals in between. Moreover, by studying the cuticle it is rarely possible to determine the exact boundary between host and transplanted epidermis. These disadvantages can be overcome by using a colour mutant⁵ which enables continuous observation of the transplanted cells.

In the wild type of *Dysdercus intermedius* from the third larval instar onwards the anterior zone of the third ventral abdominal segment is red and the posterior zone white. The mutant lacks the red pigment and therefore the anterior zone looks grey. It should be noted that the pigment is located inside the epidermal cells. The cuticle is transparent and permits direct observation of the location and possible movements of the transplanted cells. Transplantations were carried out on third instar larvae as described by Lawrence *et al.*³. The transplants always included the border between the red and white zones. The hosts were of the grey mutant type. The segments carrying transplants were filmed by time-lapse cinematography (1 frame per 3 min) or photographed at daily intervals until after metamorphosis.

Three stages in the development of a transplant which had been rotated anticlockwise through 90° are illustrated in Fig. 1. After the first moult following the operation (Fig. 1*a*) some red cells are found between the white cells of the graft and

FIG. 2 Time-lapse film which was taken towards the end of the fifth larval instar. *a*, Aspect at the beginning of film (0 h); *b*, at the end (54 h) of the film. Scale, 100 μm.

the grey cells of the host (upper right). This aspect remains stationary for several days while the larva grows and mitoses occur in the epidermis⁶. When the epidermis is detached from the old cuticle in preparation for the next moult the spur at the posterior end of the red patch disappears and the wedge of red cells at the right anterior rim increases considerably in width. This aspect (Fig. 1b) persists through moulting and during the following days. Some days before metamorphosis, when the epidermis again detaches from the cuticle, the posterior region seems to move forward and the wedge at the right is strengthened again. Simultaneously, the angle between the posterior segment margin (at the bottom) and the red/white border within the transplant decreases further. The resulting pattern (Fig. 1c) is retained by the imago. It should be noted that some local peculiarities at the red/white border within the transplant (arrows) persist throughout development. During all these changes no pink cells were observed which might indicate a change of pigment synthesising activities.

The analysis of time-lapse films (Figs 2 and 3) reveals that the rotation of the red/white border with respect to the posterior segment margin and the concomitant changes in shape are accomplished within 20 to 25 h ($28 \pm 1^\circ\text{C}$).

These observations demonstrate clearly that the transplanted cells may change their positions beneath the cuticle with respect to landmarks on the host segment, while at the same time retaining to some extent their relative positions within the transplant (arrows in Fig. 1). The running time-lapse films give the impression that the transplanted cells near the margin move considerably during the motile phase. In bigger transplants the more central regions seem to be

rotated passively. This impression is compatible with the data derived by scoring several parameters at intervals (Fig. 3a and b). It therefore seems possible to explain pattern reconstitution in *Dysdercus* without assuming some kind of resetting (in this case of pigment synthesis) in the transplanted cells. Finally it may be pointed out that the change of the angle between segment margin and the red/white border corresponds to changes in ripple orientation described by Lawrence *et al.*³ in *Rhodnius*. Should the changes in this insect also be due to cell migration in the marginal parts and rotation of the central parts of the transplant, then some inconsistencies between the observed patterns and those simulated by the computer on the basis of the resetting hypothesis (their Figs 8a and 19) might be due to migration of the marginal transplant and perhaps host cells.

I thank Professor Dr K. Sander for discussions and for reading the manuscript, Dr H. Vollmar for helping me with the films, the BASF for supplying me with two stocks of *Dysdercus intermedius* Dist. and cotton seeds, and the Deutsche Forschungsgemeinschaft SFB 46 for financial support.
